Notices

Knowledge and best practice in this field are constantly changing. As new research and experience
broaden our understanding, changes in research methods, professional practices, or medical treatment
may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating
and using any information, methods, compounds, or experiments described herein. In using such
information or methods they should be mindful of their own safety and the safety of others, including
parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most
current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be
administered, to verify the recommended dose or formula, the method and duration of administration,
and contraindications. It is the responsibility of practitioners, relying on their own experience and
knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each
individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume
any liability for any injury and/or damage to persons or property as a matter of products liability,
negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas
contained in the material herein.

Sabre Foundation

*Sincerest thanks to my wonderful wife, Linda, and our children,
David and Cathy, for their patience and support.
Also, the editorial help of our three Cavalier King Charles puppies,
Winston, Humphrey, and Punkin, was invaluable.*

Gary S. Firestein

*Sincere thanks for the kind mentoring
from Edward D. Harris, Jr.,
as well as for the support of my wife, Lenore,
and my children, Graham and Laura.*

Ralph C. Budd

*To my three boys:
my dear husband, Frank Cockerill, and our two wonderful sons, Richard and Matthew,
for being my constant source of inspiration, love, and pride.
And to my parents, Huda and Ezzat, for their love and tireless support.*

Sherine E. Gabriel

*To my wife, Karin, for her patience,
understanding, and love and to our wonderful girls,
Megan and Rebecca, who continue to enlighten me.*

Iain B. McInnes

*Sincere thanks to my wife, Deb, for her patience and love
and to our wonderful children, Kim and Andy, Jennie and Dan, and Scott and Melissa.
I also want to thank the members of my division
who continue to support me in all my efforts.*

James R. O'Dell

DEDICATION

Edward D. Harris, Jr., MD
1937-2010

Edward D. “Ted” Harris, Jr., was one of the four founding editors of the *Textbook of Rheumatology*. In the late 1970s, Bill Kelley sensed the need for a text that reflected the growth of rheumatology into a mature discipline. He met with Ted, who quickly agreed, and they identified Shaun Ruddy and Clem Sledge as co-editors. A prime concern was that the new book should be grounded in the abundant information in basic science that supported our subspecialty. The standards they set were responsible for the high quality of the finished Textbook. Ted’s choice of the iconic profile of Renoir, who suffered from rheumatoid arthritis, has graced the cover of nine editions of the book and served to connect us to the humanitarian aspect of our discipline.

Ted was a graduate of Dartmouth College and its medical school and of Harvard Medical School. Following his residency at Massachusetts General Hospital he moved to the National Institutes of Health (NIH), where he engaged in research on collagen. In his spare moments he also formed a jazz ensemble, with himself playing bass. Upon Ted’s return to Mass General he entered a rheumatology fellowship and joined the laboratory of Dr. Stephen Krane, where Ted applied his knowledge of collagen to the inflammatory synovium of rheumatoid arthritis.

In 1970 Ted was recruited back to Dartmouth, where he built a robust connective tissue disease unit and received one of the NIH’s first arthritis center awards. Along with long-time colleague Dr. Constance Brinckerhoff, Ted’s group defined the role of collagenase and metalloproteinases in the rheumatoid synovium. In 1979 Ted was sole author of the seminal monograph *Rheumatoid Arthritis*, which detailed the complex interactions of the immune system with connective tissue in rheumatoid arthritis. In 1983

Rutgers Medical School recruited Ted to become Chair of Medicine, and four years later he assumed the Chair of Medicine position at Stanford, a position he held until 1995. During Ted’s career he authored well over 100 peer-reviewed publications and 70 reviews, chapters, editorials, and books.

Ted served as President of the American College of Rheumatology (ACR) and, during his tenure, skillfully helped arrange an amicable separation of the ACR and the Arthritis Foundation so that each organization could better pursue its mission. He was named a fellow of the British Royal College of Physicians in 2002 and received the Presidential Gold Medal from ACR in 2007.

Ted had a remarkably perceptive intellect and a razor wit. A former English major, his writing was crisp and vigorous. His love of language elevated and animated text. Colleagues knew that an “EDH note” could be mellifluous, mirthful, and merciless all at once. As academic secretary to Stanford, Ted’s amusing touches to the minutes of the Stanford Senate were legendary. He might squeeze in a quote from Dr. Seuss’s *Horton Hatches the Egg*, add footnotes on faculty members’ attire, or slip in sly editorial comments such as “wisely interrupted” or “introduced with appreciated brevity.” As a result, Ted’s words resonated and got results.

The English degree came in handy when, in 1997, Ted was named executive secretary of Alpha Omega Alpha (AOA) and editor of *The Pharos*, the society’s nontechnical compendium of essays, poetry, art, and articles on medical history, ethics, and health policy. Ted breathed new life and style into the journal during his 13-year tenure as editor. Ted also created a 532-page anthology called *Creative Healers: A Collection of Essays, Reviews, and Poems from The Pharos, 1938-1998*, published by AOA in 2004. Reviewers on Amazon.com have mentioned the editor’s keen eye for engaging writing, calling the volume’s contents “moving” and “a tribute to the range of interests percolating around in active intellects.”

Ted Harris mentored a generation of rheumatologists and taught us all by his example of dynamic creative thought and a deep humanitarian spirit. All of us involved with *Kelley’s Textbook of Rheumatology* feel a profound sadness with the loss of Ted, but even here Ted would provide the appropriate perspective, with a passage he wrote in a *Pharos* editorial: “Melancholy, that gray veil that takes color out of life, can, at the same time, add to the brilliance and value of life, if we feel what it is asking of us. Melancholy and sadness, similar to love, can make those compartment walls in our minds permeable, enabling us to express empathy that is truly felt within.”

Ted Harris was a consummate scholar and a great humanitarian, with a facile mind that spanned a wide array of interests from science to the arts. He was in essence a civilized man, something that has always been distinguished by its rarity.

PREFACE

Rheumatology continues to evolve and inspire as a discipline that occupies the forefront of molecular medicine and novel targeted therapies. The previous edition of the Textbook built on a proud heritage of excellence but was distinguished by change: new editors, more color, new online access, and many other features. Matching the extraordinary pace of change in our field, this new edition continues a grand tradition by accelerating our commitment to excellence in the face of the changing world of publishing. The most obvious examples are the editors for this edition. Three distinguished and longtime colleagues, “The Three Amigos” who were the heart and soul of the Textbook for a generation, have stepped down: Shaun Ruddy, John Sergeant, and Ted Harris. Ted passed away recently but left a legacy that will endure (see dedication to the 9th edition). Finding new editors of such high caliber was daunting, but fortunately we met the challenge when we convinced Jim O'Dell and Sherine Gabriel to join our intrepid crew. They brought incredible new strength and expertise, especially in clinical medicine, clinical trials, outcomes research, and epidemiology.

The 9th edition includes a multitude of new authors and chapters. Improved graphics and more easily accessible online content are also features of this edition. The print edition now limits the number of references because we

preferred to use allotted pages for scientific content rather than long lists of articles. The complete citations are, however, still available online.

The initial preparative stages of the book occurred, like the last edition, in Costa Rica, where we slaved away for days on the Table of Contents and in selecting an outstanding group of authors. We admit that some fun and entertainment occurred as well, organized and supervised by Linda Lyons Firestein, MD. We also thank the Elsevier staff who braved the rigors of tropical paradise with us, Pam Hetherington and Janice Gaillard. But mostly we want to thank the authors who put in countless hours writing chapters and putting up with our constant haranguing out of love for our discipline, readers, and students.

We hope that you enjoy the Textbook as much as we enjoyed preparing it. The journey has been a formidable and gratifying collegial effort. Because our “Textbook of Rheumatology Costa Rica” Headquarters was sold in 2011, we are searching the globe for alternative sites when it is time to prepare the 10th edition. Although we do not yet know how the next edition will evolve, one certainty is that it will continue the tradition of excellence.

The Editors

Biology of the Normal Joint

STEVEN R. GOLDRING • MARY B. GOLDRING

KEY POINTS

Condensation of mesenchymal cells, which differentiate into chondrocytes, results in formation of cartilage anlagen, which provide the template for the developing skeleton.

During development of the synovial joint, growth differentiation factor-5 regulates interzone formation, and interference with movement of the embryo during development impairs joint cavitation.

Members of the bone morphogenetic protein/transforming growth factor- β , fibroblast growth factor, and Wnt families and the parathyroid hormone–related peptide/Indian hedgehog axis are essential for joint development and growth plate formation.

The synovial lining of diarthrodial joints is a thin layer of cells lacking a basement membrane and consisting of two principal cell types: macrophages and fibroblasts.

The articular cartilage receives its nutritional requirements via diffusion from the synovial fluid, and interaction of the cartilage with components of the synovial fluid contributes to the unique low-friction surface properties of the articular cartilage.

CLASSIFICATION OF JOINTS

Human joints provide the structures by which bones join with one another and may be classified according to histologic features of the union and range of joint motion. Three classes of joint design have been identified: (1) synovial or diarthrodial joints (Figure 1-1), which articulate with free movement, have a synovial membrane lining the joint cavity, and contain synovial fluid; (2) amphiarthroses, in which adjacent bones are separated by articular cartilage or a fibrocartilage disk and are bound by firm ligaments permitting limited motion (e.g., pubic symphysis, intervertebral disks of vertebral bodies, distal tibiofibular articulation, sacroiliac joint articulation with pelvic bones); and (3) synarthroses, which are found only in the skull (suture lines), where thin, fibrous tissue separates adjoining cranial plates that interlock to prevent detectable motion before the end of normal growth, yet permit growth in childhood and adolescence.¹

Joints also can be classified according to the connective tissues present. Symphyses have a fibrocartilaginous disk separating bone ends that are joined by firm ligaments (e.g., symphysis pubis and intervertebral joints). In synchondroses, the bone ends are covered with articular cartilage, but no synovium or significant joint cavity is present (e.g., sternomanubrial joint). In syndesmoses, the bones are joined directly by fibrous ligaments without a cartilaginous interface (the distal tibiofibular articulation is the only joint of this type outside the cranial vault). In synostoses, bone bridges are formed between bones, producing ankylosis.

Synovial joints, which are classified further according to their shapes, include ball-and-socket (hip), hinge (interphalangeal), saddle (first carpometacarpal), and plane (patellofemoral) joints. These configurations reflect varying functions, as the shapes and sizes of opposing surfaces determine the direction and extent of motion. The various designs permit flexion, extension, abduction, adduction, or rotation. Certain joints can act in one (humeroulnar), two (wrist), or three (shoulder) axes of motion.

This chapter concentrates on the developmental biology and relationship between structure and function of a “prototypic,” “normal” human diarthrodial joint—the joint most likely to develop arthritis. Most research that has been done concerns the knee because of its accessibility, but other joints are described when appropriate.

DEVELOPMENTAL BIOLOGY OF THE DIARTHRODIAL JOINT

Skeletal development is initiated by the differentiation of mesenchymal cells that arise from three sources: (1) neural crest cells of the neural ectoderm that gives rise to craniofacial bones; (2) the sclerotome of the paraxial mesoderm, or somite compartment, which forms the axial skeleton; and (3) the somatopleure of the lateral plate mesoderm, which yields the skeleton of the limbs.² The appendicular skeleton develops in the human embryo from limb buds, which first are visible at around 4 weeks of gestation. Structures resembling adult joints are generated at approximately 4 to 7 weeks of gestation.³ Many other crucial phases of musculoskeletal development follow, including vascularization of

Figure 1-1 A normal human interphalangeal joint, in sagittal section, as an example of a synovial, or diarthrodial, joint. The tidemark represents the calcified cartilage that bonds articular cartilage to the subchondral bone plate. (From Sokoloff L, Bland JH: *The musculoskeletal system*, Baltimore, 1975, Williams & Wilkins. © 1975, Williams & Wilkins Co, Baltimore.)

epiphyseal cartilage (8 to 12 weeks), appearance of villous folds in synovium (10 to 12 weeks), evolution of bursae (3 to 4 months), and appearance of periarticular fat pads (4 to 5 months).

The upper limbs develop approximately 24 hours earlier than analogous portions of the lower limbs. Proximal structures, such as the glenohumeral joint, develop before more distal ones, such as the wrist and hand. As a consequence, insults to embryonic development during limb formation affect a more distal portion of the upper limb than of the lower limb. Long bones are formed as a result of replacement of the cartilage template by endochondral ossification. The stages of limb development are well described by O’Rahilly and Gardner^{3,4} and are shown in Figure 1-2. The developmental sequence of events occurring during synovial joint formation and some of the regulatory factors and extracellular matrix components involved are summarized in Figures 1-3 and 1-4.

Interzone Formation and Joint Cavitation

The morphology of the developing synovial joint and the process of joint cavitation have been described in many classic studies done on the limbs of mammalian and avian embryos.⁵ In the human embryo, cartilage condensations, or chondrifications, can be detected at stage 17, when the embryo is small, approximately 11.7 mm long.^{3,4} In the region of the future joint, following formation of the homogeneous chondrogenic interzone at 6 weeks (stages 18 and 19), a three-layered interzone is formed at approximately 7 weeks (stage 21), which consists of two chondrogenic,

Figure 1-2 The development of a synovial joint. **A**, Condensation. Joints develop from the blastema, not the surrounding mesenchyme. **B**, Chondrification and formation of the interzone. The interzone remains avascular and highly cellular. **C**, Formation of synovial mesenchyme. Synovial mesenchyme forms from the periphery of the interzone and is invaded by blood vessels. **D**, Cavitation. Cavities are formed in the central and peripheral interzone and merge to form the joint cavity. **E**, The mature joint. (From O’Rahilly R, Gardner E: *The embryology of movable joints*. In Sokoloff L, editor: *The joints and synovial fluid*, vol 1, New York, 1978, Academic Press.)

perichondrium-like layers that cover the opposing surfaces of the cartilage anlagen and are separated by a narrow band of densely packed cellular blastema that remains and forms the interzone. Cavitation begins in the central interzone at about 8 weeks (stage 23).

Although these cellular events associated with joint formation have been recognized for many years, only recently have the genes regulating these processes been elucidated. These genes include growth differentiation factor (GDF)-5, Wnt-14, bone morphogenetic protein (BMP)-2, BMP-4, BMP-6, BMP-7, and the GDF-BMP antagonists.⁵⁻⁸ In addition, joint formation is accompanied by the expression of several fibroblast growth factor (FGF) family members, including FGF-2 and FGF-4.⁹ The balance of signaling between BMP and FGF determines the rate of proliferation, adjusting the pace of differentiation.¹⁰ Two transcription factors, Cux-1, a homeobox factor, and the ETS factor ERG/C-1-1, are expressed concurrently with GDF-5 and Wnt-14 at the onset of joint formation.^{11,12} Hartmann and Tabin¹³ have proposed two major roles for Wnt-14. First, it acts at the onset of joint formation as a negative regulator of chondrogenesis. Second, it facilitates interzone formation and cavitation by inducing expression of GDF-5 (also known as *cartilage-derived morphogenetic protein-1* [CDMP-1]), Wnt-4, chordin, and the hyaluronan receptor, CD44.¹³⁻¹⁵ Paradoxically, application of GDF-5 to developing joints in mouse embryo limbs in organ culture causes joint fusion,¹⁶ suggesting that temporospatial interactions among distinct cell populations are important for the correct

response. The current view is that GDF-5 is required at early stages of condensation, where it stimulates recruitment and differentiation of chondrogenic cells, and later, when its expression is restricted to the interzone.

The distribution of collagen types and keratan sulfate in developing avian and rodent joints has been characterized by immunohistochemistry.¹⁷⁻²¹ Collagen types I and III

characterize the matrix produced by mesenchymal cells, which switch to the production of types II, IX, and XI collagens that typify the cartilaginous matrix at the time of condensation.²² The messenger RNAs (mRNAs) encoding the small proteoglycans, biglycan and decorin, may be expressed at this time, but the proteins do not appear until after cavitation in the regions destined to become articular

cartilage.²³ Interzone regions are marked by the expression of type IIA collagen by chondrocyte progenitors in the perichondrial layers, type IIB and XI collagens by overt chondrocytes in the cartilage anlagen, and type I collagen in the interzone and in the developing capsule and perichondrium (Figure 1-5).²⁴

The interzone region contains cells in two outer layers that are destined to differentiate into chondrocytes and become incorporated into the epiphyses, and in a thin intermediate zone that are programmed to undergo joint cavitation and may remain as articular chondrocytes.²⁵ Fluid and macromolecules accumulate in this space, creating a nascent synovial cavity. Blood vessels appear in the surrounding capsuloseynovial blastemal mesenchyme before separation of adjacent articulating surfaces.²⁶ Although it was first assumed that these interzone cells should undergo necrosis or

programmed cell death (apoptosis),²⁷ some investigators have found no evidence of DNA fragmentation preceding cavitation.^{24,25,28,29} Evidence that metalloproteinases are involved in loss of tissue strength in the region undergoing cavitation is also lacking.³⁰ Instead, the actual joint cavity seems to be formed by mechanospacial changes induced by the synthesis of hyaluronan via uridine diphosphoglucose dehydrogenase (UDPGD) and hyaluronan synthase. The interaction of hyaluronan with its cell surface receptor, CD44, modulates cell migration, but it is thought that the accumulation of hyaluronan and the associated mechanical influences play a major role in forcing the cells apart and inducing rupture of the intervening extracellular matrix by tensile forces.^{20,30} This mechanism accounts for the observation that joint cavitation is incomplete in the absence of movement.^{31,32} Equivalent data from human embryonic

Figure 1-5 In situ hybridization of a 13-day-old (stage 39) chicken embryo middle digit, proximal interphalangeal joint, midfrontal sections. **A**, Bright-field image shows developing joint and capsule (C). **B**, Equivalent paraffin section of opposite limb of same animal shows onset of cavitation laterally (arrow). **C**, Expression of type IIA collagen mRNA in articular surface cells, perichondrium, and capsule. **D**, Type IIB collagen mRNA is expressed only in chondrocytes of the anlagen. **E**, Type XI collagen mRNA is expressed in the surface cells, perichondrium, and capsule, with lower levels in chondrocytes. **F**, Type I collagen mRNA is present in cells of the interzone and capsule. **C** through **F** images are dark field. Calibration bar = 1 μ m. (From Nalin AM, Greenlee TK Jr, Sandell LJ: Collagen gene expression during development of avian synovial joints: transient expression of types II and XI collagen genes in the joint capsule, *Develop Dyn* 203:352–362, 1995.)

joints are difficult to obtain. In all large joints in humans, complete joint cavities are apparent at the beginning of the fetal period.

CARTILAGE FORMATION AND ENDOCHONDRAL OSSIFICATION

The skeleton develops from the primitive, avascular, densely packed cellular mesenchyme, termed the *skeletal blastema*. Common precursor mesenchymal cells divide into chondrogenic, myogenic, and osteogenic lineages that determine the differentiation of cartilage centrally, muscle peripherally, and bone. Surrounding tissues, particularly epithelium, influence the differentiation of mesenchymal progenitor cells to chondrocytes in cartilage anlagen. The cartilaginous nodules appear in the middle of the blastema; simultaneously, cells at the periphery become flattened and elongated to form the perichondrium. In the vertebral column, cartilage disks arise from portions of the somites surrounding the notochord, and nasal and auricular cartilage and the embryonic epiphysis form from the perichondrium. In the limb, the cartilage remains as a resting zone that later becomes the articular cartilage, or it undergoes terminal hypertrophic differentiation to become calcified (growth plate formation) and is replaced by bone (endochondral ossification). The latter process requires extracellular matrix remodeling and vascularization (angiogenesis). These events are controlled exquisitely by cellular interactions with the surrounding matrix, growth and differentiation factors, and other environmental factors that initiate or suppress cellular signaling pathways and transcription of specific genes in a temporospatial manner.

Condensation and Limb Bud Formation

Formation of cartilage anlagen occurs in four stages: (1) cell migration, (2) aggregation regulated by mesenchymal-epithelial cell interactions, (3) condensation, and (4) overt chondrocyte differentiation, or chondrification.^{3,4,33} Interactions with the epithelium determine mesenchymal cell recruitment and migration, proliferation, and condensation.^{3,4,34} The aggregation of chondroprogenitor mesenchymal cells into precartilage condensations was first described by Fell³³ and depends on signals initiated by cell-cell and cell-matrix interactions, the formation of gap junctions, and changes in the cytoskeletal architecture. Before condensation, the prechondrocytic mesenchymal cells produce extracellular matrix that is rich in hyaluronan and type I collagen and type IIA collagen, which contains the exon-2–encoded aminopropeptide found in noncartilage collagens.³⁵ The initiation of condensation is associated with increased hyaluronidase activity and the appearance of cell adhesion molecules, neural cadherin (N-cadherin), and the neural cell adhesion molecule (N-CAM), all of which facilitate cell-cell interactions.

Before chondrocyte differentiation, cell-matrix interactions are facilitated by fibronectin binding to syndecan, downregulating N-CAM and setting condensation boundaries. Increased cell proliferation and extracellular matrix remodeling, with the disappearance of type I collagen, fibronectin, and N-cadherin, and the appearance of tenascins, matrilins, and thrombospondins, including cartilage

oligomeric protein, initiate the transition from chondroprogenitor cells to a fully committed chondrocyte.^{2,36-38} N-cadherin and N-CAM disappear in differentiating chondrocytes and are detectable later only in perichondrial cells. The differentiated chondrocytes can proliferate and undergo the complex process of hypertrophic maturation or remain within cartilage elements in articular joints.

Zwilling³⁹ proposed that positional information for organization of the limb bud was impacted by diffusible agents generated at the tip of the limb bud and along its posterior margin, promoting the development of a cartilaginous anlage along proximal-distal and anterior-posterior axes. Limb buds develop from the lateral plate mesoderm.⁴⁰ Patterning of limb mesenchyme is the result of interactions between the mesenchyme and the overlying epithelium.⁴¹ The embryonic limb possesses two signaling centers: the apical ectodermal ridge (AER) and the zone of polarizing activity (ZPA), which produce signals responsible for directing proximal-distal outgrowth (AER) and anterior-posterior patterning (ZPA).^{2,36}

Much of our current understanding of limb development is based on early studies in chickens and more recently in mice. Regulatory events are controlled by interacting patterning systems involving FGF, hedgehog, BMP, and Wnt pathways, each of which functions sequentially over time (see Figure 1-3).⁴⁰ Wnt signaling via β -catenin is required to induce FGFs, such as FGF-10 and FGF-8, which act in positive feedback loops.^{40,42} FGF-2, FGF-4, and FGF-8 (induced by Wnt-3A⁴³), from specialized epithelial cells in the AER that are covering the limb bud tip, control proximal-distal (shoulder/finger) outgrowth.⁴⁴ The homeobox (Hox) transcription factors encoded by HoxA and HoxD gene clusters, which are crucial for early events of limb patterning in the undifferentiated mesenchyme, are required for the expression of FGF-8 and Sonic hedgehog (Shh),⁴⁵ and they modulate the proliferation of cells within the condensations.³³ Among the Hox genes, *Hoxa13* and *Hoxd13* enhance and *Hoxa11* and *Hoxd11* suppress early events in the formation of cartilage anlagen.

Wnt-7A is expressed early during limb bud development, where it acts to maintain Shh expression.⁴⁰ Shh, produced by a small group of cells in the posterior zone of the ZPA (in response to retinoic acid in the mesoderm⁴⁶ and FGF-4 in the AER⁴⁷), plays a key role in directing anterior-posterior (e.g., little finger/thumb) patterning^{46,48} and in stimulating expression of BMP-2, BMP-4, BMP-7, and Hox genes.⁴⁹⁻⁵¹ Shh signaling, which is required for early limb patterning, but not for limb formation, is mediated by the Shh receptor Patched (Ptc1), which activates another transmembrane protein, Smoothened (Smo), and inhibits processing of the Gli3 transcription factor to a transcriptional repressor.^{42,52} Dorsal-ventral (e.g., knuckles/palm) patterning depends on secretion of Wnt-7A⁵³ and expression of the following transcription factors: radical fringe (r-Fng) by the dorsal ectoderm, and engrailed (En-1) and Lmx1b (which is induced by Wnt-7A) by the ventral endoderm.^{42,54}

BMP-2, BMP-4, and BMP-7 coordinately regulate the patterning of limb elements within condensations depending on the temporal and spatial expression of BMP receptors and BMP antagonists, such as noggin and chordin, as well as the availability of SMADs (signaling mammalian homologs of *Drosophila* mothers against decapentaplegic).^{40,55-57}

In vitro and in vivo studies have shown that BMP signaling is required for the formation of precartilaginous condensations and for the differentiation of precursors into chondrocytes.⁵⁸ Growth of the condensation ceases when noggin inhibits BMP signaling and permits overt differentiation to chondrocytes, which often are designated as *chondroblasts*. The cartilage formed serves as a template for formation of cartilage elements in the vertebra, sternum, and rib, and for limb elongation or endochondral bone formation.

Molecular Signals in Cartilage Morphogenesis and Growth Plate Development

The cartilage anlagen grow by cell division and deposition of the extracellular matrix and by apposition of proliferating cells from the inner chondrogenic layer of the perichondrium. The nuclear transcription factor, Sox9, is one of the earliest markers expressed in cells undergoing condensation and is required for the subsequent stage of chondrogenesis characterized by the deposition of matrix containing collagens II, IX, and XI and aggrecan in the cartilage anlagen.^{59,60} Two additional Sox family members, L-Sox5 and Sox6, which are not present in early mesenchymal condensations but are coexpressed with Sox9 during chondrocyte differentiation,⁶¹ have a high degree of sequence identity with each other but have no sequence homology with Sox9, except in the high-mobility group (HMG) box. They can form homodimers or heterodimers, which bind more efficiently to pairs of HMG box sites than to single sites, and in contrast to Sox9, they contain no transcriptional activation domain. The expression of SOX proteins depends on BMP signaling via BMPRI A and BMPRI B, which are functionally redundant and active in chondrocyte condensations but not in the perichondrium.⁵⁸ L-Sox5 and Sox6 are required for the expression of Col9a1, aggrecan, link protein, and Col2a1 during overt chondrocyte differentiation.⁶² The runt domain transcription factor, Runx2 (also known as *core binding factor*, Cbfa1), is expressed in all condensations, including those that are destined to form bone.⁶³⁻⁶⁵

Throughout chondrogenesis, the balance of signaling by BMPs and FGFs determines the rate of proliferation while adjusting the pace of differentiation.¹⁰ In the long bones, long after condensation, BMP-2, BMP-3, BMP-4, BMP-5, and BMP-7 are expressed primarily in the perichondrium, and only BMP-7 is expressed in the proliferating chondrocytes.¹⁰ BMP-6 is found later exclusively in hypertrophic chondrocytes along with BMP-2. More than 23 FGFs have been identified so far.⁶⁶ The specific ligands that activate each FGF receptor (R) during chondrogenesis in vivo have been difficult to identify because signaling depends on the temporal and spatial location of not only the ligands, but also the receptors.⁶⁷ FGFR2 is upregulated early in condensing mesenchyme and is present later in the periphery of the condensation along with FGFR1, which is expressed in surrounding loose mesenchyme. FGFR3 is associated with proliferation of chondrocytes in the central core of the mesenchymal condensation and may overlap with FGFR2. Proliferation of chondrocytes in the embryonic and postnatal growth plate is regulated by multiple mitogenic stimuli, including FGFs, which converge on cyclin D1.⁶⁸

In the growth plate, FGFR3 serves as a master inhibitor of chondrocyte proliferation via phosphorylation of the Stat1 transcription factor, which increases expression of the cell cycle inhibitor p21.⁶⁹ More recent studies suggest that FGF-18 is the preferred ligand of FGFR3 because Fgf18-deficient mice have an expanded zone of proliferating chondrocytes similar to that in Fgfr3-deficient mice, and that FGF-18 can inhibit Indian hedgehog (Ihh) expression.⁷⁰ FGF-18 and FGF-9 are expressed in the perichondrium and periosteum and form a functional gradient from the proximal proliferating zone, where FGF-18 acts via FGFR3 to downregulate proliferation and subsequent maturation.^{70,71} FGF-18 and FGF-9 interact with FGFR1 in the prehypertrophic and hypertrophic zones, where more recent evidence indicates that they regulate vascular invasion by inducing the expression of vascular endothelial growth factor (VEGF) and VEGFR1. As the epiphyseal growth plate develops, FGFR3 disappears, and FGFR1 expression is upregulated in prehypertrophic and hypertrophic chondrocytes, suggesting a role for FGFR1 in the regulation of cell survival and differentiation and possibly cell death.⁶⁷

The proliferation of chondrocytes in the lower proliferative and prehypertrophic zones is under the control of a local negative feedback loop involving signaling by parathyroid hormone-related protein (PTHrP) and Ihh.⁷² Ihh expression is restricted to the prehypertrophic zone, and the PTHrP receptor is expressed in the distal zone of periarticular chondrocytes. Adjacent, surrounding perichondrial cells express the Hedgehog receptor patched (Ptc), which on Ihh binding, similar to Shh in the mesenchymal condensations, activates Smo and induces Gli transcription factors; this can feedback regulate Ihh target genes in a positive (*Gli1* and *Gli2*) or negative (*Gli3*) manner.⁷³ Ihh induces expression of PTHrP in the perichondrium,⁷⁴ and PTHrP signaling stimulates cell proliferation via its receptor expressed in the periarticular chondrocytes.⁷⁵ These interactions are modulated by a balance of BMP and FGF signaling that adjusts the pace of chondrocyte terminal differentiation to the proliferation rate.¹⁰ FGF-18 or FGFR3 signaling can inhibit Ihh expression,⁷⁰ and BMP signaling upregulates the expression of Ihh in cells that are beyond the range of the PTHrP-induced signal.¹⁰ Evidence indicates that Ihh acts independently of PTHrP on periarticular chondrocytes to stimulate differentiation of columnar chondrocytes in the proliferative zone, whereas PTHrP acts by preventing premature differentiation into prehypertrophic and hypertrophic chondrocytes, suppressing premature expression of Ihh.⁷⁶ Ihh and PTHrP, by transiently inducing proliferation markers and repressing differentiation markers, function in a temporospatial manner to determine the number of cells that remain in the chondrogenic lineage versus the number that enter the endochondral ossification pathway.^{72,77}

Endochondral Ossification

The development of long bones from the cartilage anlagen occurs by a process termed *endochondral ossification*, which involves terminal differentiation of chondrocytes to the hypertrophic phenotype, cartilage matrix calcification, vascular invasion, and ossification (see Figure 1-4).^{28,77-79} This process is initiated when cells in the central region of the

anlage begin to hypertrophy, increasing cellular fluid volume by almost 20 times. *Ihh* plays a pivotal role in regulating endochondral bone formation by synchronizing perichondrial maturation with chondrocyte hypertrophy, which is essential for initiating the process of vascular invasion.⁸⁰ *Ihh* is expressed in prehypertrophic chondrocytes as they exit the proliferative phase and enter the hypertrophic phase, at which time they begin to express the hypertrophic chondrocyte marker, type X collagen (Col10a1), and alkaline phosphatase. These cells are responsible for laying down the cartilage matrix, which subsequently undergoes mineralization.

Runx2, which serves as a positive regulatory factor in chondrocyte maturation to hypertrophy,⁸¹ is expressed in the adjacent perichondrium and in prehypertrophic chondrocytes, but less in late hypertrophic chondrocytes,^{82,83} overlapping with *Ihh*, Col10a1, and BMP-6.^{77,84} BMP-induced Smad1 interacts with Runx2, and Runx2 and Smad1 are important for chondrocyte hypertrophy.^{81,85,86} An essential role for Runx2 in the process of chondrocyte hypertrophy is supported by the observation that terminal differentiation is blocked in Runx2-deficient mice.^{64,87} Interactions with components of the extracellular matrix also contribute to regulation of the process of chondrocyte terminal differentiation. Matrix metalloproteinase (MMP)-13, a downstream target of Runx2, is expressed by terminal hypertrophic chondrocytes,⁸⁸⁻⁹¹ and MMP-13 deficiency results in significant interstitial collagen accumulation, leading to a delay in endochondral ossification in the growth plate with increased length of the hypertrophic zone.^{92,93}

In contrast, Col10a1 knockout mice and transgenic mice with a dominant interference *Col10a1* mutation have subtle growth plate phenotypes with compressed proliferative and hypertrophic zones and altered mineral deposition.⁹⁴ Mutations in the *COL10a1* gene are associated with the dwarfism observed in human chondrodysplasias. These mutations affect regions of the growth plate that are under great mechanical stress, and it has been suggested that the defect in skeletal growth may be due in part to alteration of the mechanical integrity of the pericellular matrix in the hypertrophic zone, although a role for defective vascularization also has been proposed.⁹⁵ The extracellular matrix remodeling that accompanies chondrocyte terminal differentiation is thought to induce an alteration in the environmental stress experienced by hypertrophic chondrocytes, which eventually undergo apoptosis.^{77,96,97} Together these studies indicate that the composition and remodeling of the extracellular matrix play an important role in processes associated with chondrocyte hypertrophy, vascular invasion, and, as discussed subsequently, osteoblast recruitment and subsequent bone formation.⁹⁰

Vascular invasion of the hypertrophic zone is required for the replacement of calcified cartilage by bone.^{84,91} The angiogenic factor, VEGF, promotes vascular invasion by specifically activating localized receptors, including Flk expressed in endothelial cells in the perichondrium or surrounding soft tissues, neuropilin 1 (Npn1) expressed in late hypertrophic chondrocytes, or Npn2 expressed exclusively in the perichondrium.²⁸ VEGF is expressed as three different isoforms: VEGF188, a matrix-bound form, is essential for metaphyseal vascularization, whereas the soluble form,

VEGF120 (VEGFA), regulates chondrocyte survival and epiphyseal cartilage angiogenesis.⁹⁸⁻¹⁰⁰ VEGF164 can be soluble or matrix bound and may act directly on chondrocytes via Npn2. VEGF is released from the extracellular matrix by MMPs, including MMP-9, membrane-type (MT)1-MMP (MMP-14), and MMP-13. MMP-9 is expressed by endothelial cells that migrate into the central region of the hypertrophic cartilage.⁹⁰ MMP-14, which has a broader range of expression than MMP-9, is essential for chondrocyte proliferation and secondary ossification,¹⁰¹ whereas MMP-13 is found exclusively in late hypertrophic chondrocytes.⁸² These events of cartilage matrix remodeling and vascular invasion are required for the migration and differentiation of osteoclasts and osteoblasts, which remove the mineralized cartilage matrix and replace it with bone.

Development of the Joint Capsule and Synovium

The interzone and the contiguous perichondrial envelope, of which the interzone is a part, contain the mesenchymal cell precursors that give rise to other joint components, including the joint capsule, synovial lining, menisci, intracapsular ligaments, and tendons.^{3,4,102,103} The external mesenchymal tissue condenses as a fibrous capsule. The peripheral mesenchyme becomes vascularized and is incorporated as the synovial mesenchyme, which differentiates into a pseudomembrane at about the same time as cavitation begins in the central interzone (stage 23, approximately 8 weeks). The menisci arise from eccentric portions of the articular interzone. In common usage, the term *synovium* refers to the true synovial lining and the subjacent vascular and areolar tissue, up to—but excluding—the capsule. Synovial lining cells can be distinguished as soon as multiple cavities within the interzone begin to coalesce. At first, these are exclusively fibroblast-like (type B) cells.

As the joint cavity increases in size, synovial lining cell layers expand through proliferation of fibroblast-like cells and recruitment of macrophage-like (type A) cells from the circulation.¹⁰⁴ The synovial lining cells express the hyaluronan receptor, CD44, and UDPGD, the levels of which remain elevated after cavitation. This increased activity likely contributes to the high concentration of hyaluronan in joint fluids.^{30,105} Further synovial expansion results in the appearance of synovial villi at the end of the second month, early in the fetal period, which greatly increases the surface area available for exchange between the joint cavity and the vascular space. Cadherin-11 is an additional molecule expressed by synovial lining cells.^{106,107} It is essential for establishment of synovial lining architecture during development, where its expression correlates with cell migration and tissue outgrowth of the synovial lining.

The role of innervation in the developing joint is not well understood. A dense capillary network develops in the subsynovial tissue, with numerous capillary loops that penetrate into the true synovial lining layer. The human synovial microvasculature is already innervated by 8 weeks (stage 23) of gestation, around the time of joint cavitation,¹⁰² as is shown by immunoreactivity for the neuronal “housekeeping” enzymes.¹⁰⁸ Evidence of neurotransmitter

function is not found until much later, however, with the appearance of the sensory neuropeptide, substance P, at 11 weeks. The putative sympathetic neurotransmitter, neuropeptide Y, appears at 13 weeks of gestation, along with the catecholamine-synthesizing enzyme tyrosine hydroxylase. The finding that the *Slit2* gene, which functions for the guidance of neuronal axons and neurons, is expressed in the mesenchyme adjacent to the AER (stages 20 to 22) and in the peripheral mesenchyme of the limb bud (stages 23 to 28) suggests that innervation is an integral part of synovial joint development.¹⁰⁹

Development of Nonarticular Joints

In contrast to articular joints, the temporomandibular joint develops slowly, with cavitation at a crown-rump length of 57 to 75 mm (i.e., well into the fetal stage).¹¹⁰ This slow development may occur because this joint develops in the absence of a continuous blastema and involves the insertion between bone ends of a fibrocartilaginous disk that arises from muscular and mesenchymal derivatives of the first pharyngeal arch.

The development of other types of joints, such as synarthroses, is similar to that of diarthrodial joints, except that cavitation does not occur and synovial mesenchyme is not formed. In these respects, synarthroses and amphiarthroses resemble the “fused” peripheral joints induced by paralyzing chicken embryos,¹¹¹ and they may develop as they do because there is relatively little motion during their formation.

Human vertebrae and intervertebral disks develop as units, each derived from a homogeneous blastema arising from a somite. Each embryonic intervertebral disk serves as a rostral and caudal chondrogenic zone for the two adjacent evolving vertebral bodies. The periphery of the embryonic “disk” is replaced by the annulus fibrosus.¹¹² The intervertebral disk bears many similarities to the joint; the annulus is the joint capsule, the nucleus pulposus is the joint cavity, and the vertebral end plates are the cartilage-covered bone ends composing the articulation. The proteoglycans and collagens expressed during development of the intervertebral disk have been mapped and reflect the complex structure-function relationships that allow flexibility and resistance to compression in the spine.¹¹³⁻¹¹⁶

Development of Articular Cartilage

In the vertebrate skeleton, cartilage is the product of cells from three distinct embryonic lineages. Craniofacial cartilage is formed from cranial neural crest cells, the cartilage of the axial skeleton (intervertebral disks, ribs, and sternum) forms from paraxial mesoderm (somites), and the articular cartilage of the limbs is derived from the lateral plate mesoderm.² In the developing limb bud, mesenchymal condensations, followed by chondrocyte differentiation and maturation, occur in digital zones, whereas undifferentiated mesenchymal cells in the interdigital web zones undergo cell death.¹¹⁷ Embryonic cartilage is destined for one of several fates: It can remain as permanent cartilage, as on the articular surfaces of bones, or it can provide a template for the formation of bones by endochondral ossification. During development, chondrocyte maturation expands

from the central site of the original condensation, which forms the cartilage anlage resembling the shape of the future bone, toward the ends of the forming bones. During joint cavitation, the peripheral interzone is absorbed into each adjacent cartilaginous zone, evolving into the articular surface. The articular surface is destined to become a specialized cartilaginous structure that does not normally undergo vascularization and ossification.

More recent evidence indicates that postnatal maturation of the articular cartilage involves an appositional growth mechanism originating from progenitor cells at the articular surface, rather than by an interstitial mechanism.¹¹⁴ The chondrocytes of mature articular cartilage are terminally differentiated cells that are capable of expressing cartilage-specific matrix molecules, such as type II collagen and aggrecan (see following section).^{19,21,24} Through the processes described previously, the articular joint spaces are developed and are lined on all surfaces by cartilage or by synovial lining cells. These two different tissues merge at the enthesis, the region at the periphery of the joint where the cartilage melds into bone, and where ligaments and the capsule are attached.¹¹⁸ In the postnatal growth plate, differentiation of the perichondrium also is linked to differentiation of the chondrocytes in the epiphysis to form the different zones of the growth plate, contributing to longitudinal bone growth.^{28,77}

ORGANIZATION AND PHYSIOLOGY OF THE MATURE JOINT

The unique structural properties and biochemical components of diarthrodial joints make them extraordinarily durable load-bearing devices.¹¹⁹ The mature diarthrodial joint is a complex structure, influenced by its environment and by mechanical demands (see Chapter 6). Structural differences between joints are determined by their different functions. The shoulder joint, which demands an enormous range of motion, is stabilized primarily by muscles, whereas the hip, requiring motion and antigravity stability, has an intrinsically stable ball-and-socket configuration. Components of the “typical” synovial joint include synovium, muscles, tendons, ligaments, bursae, menisci, articular cartilage, and subchondral bone. The anatomy and physiology of muscles are described in detail in Chapter 5.

Synovium

The synovium lines the joint cavity and is the site of production of synovial fluid that provides nutrition for the articular cartilage and lubricates the cartilage surfaces. It is a thin membrane between the fibrous joint capsule and the fluid-filled synovial cavity that attaches to skeletal tissues at the bone-cartilage interface and does not encroach on the surface of the articular cartilage. It is divided into functional compartments: the lining region (synovial intima), the subintimal stroma, and the neurovasculature (Figure 1-6). The synovial intima, also termed *synovial lining*, is the superficial layer of the normal synovium that is in contact with the intra-articular cavity.^{105,120} The synovial lining is loosely attached to the subintima, which contains blood vessels, lymphatics, and nerves. Capillaries and arterioles generally

Figure 1-6 **A**, Schematic representation of normal human synovium. The intima contains specialized fibroblasts expressing vascular cell adhesion molecule-1 (VCAM-1) and uridine diphosphoglucose (UDPG) and specialized macrophages expressing FcγRIIIa. The deeper subintima contains unspecialized counterparts. **B**, Microvascular endothelium in human synovium contains receptors for the vasodilator/growth factor substance P. Silver grains represent specific binding of [¹²⁵I]Bolton Hunter-labeled substance P to synovial microvessels (arrows). Arrowheads indicate the synovial surface. Emulsion-dipped in vitro receptor autoradiography preparations with hematoxylin and eosin counterstain. Calibration bar = 1 μm. (**A**, From Edwards JCW: *Fibroblast biology: development and differentiation of synovial fibroblasts in arthritis*, *Arthritis Res* 2:344–347, 2000.)

are located directly underneath the synovial intima, whereas venules are located closer to the joint capsule.

A transition from loose to dense connective tissue occurs from the joint cavity to the capsule. Most cells in the normal subintimal stroma are fibroblasts and macrophages, although adipocytes and occasional mast cells are present.¹⁰⁵ These compartments are not circumscribed by basement membranes but nonetheless have distinct functions; they are separated from each other by chemical barriers, such as membrane peptidases, which limit the diffusion of regulatory factors between compartments. Synovial compartments are unevenly distributed within a single joint. Vascularity is high at the enthesis, where synovium, ligament, and cartilage coalesce.¹²¹ Far from being a homogeneous tissue in continuity with the synovial cavity, synovium is highly heterogeneous, and synovial fluid may be poorly representative of the tissue-fluid composition of any synovial tissue compartment. In rheumatoid arthritis, the synovial lining of diarthrodial joints is the site of the initial inflammatory process.^{122,123} This lesion is characterized by proliferation of synovial lining cells, increased vascularization, and infiltration of the tissue by inflammatory cells, including lymphocytes, plasma cells, and activated macrophages (see Chapter 53).¹²⁴⁻¹²⁶

Synovial Lining

The synovial lining, a specialized condensation of mesenchymal cells and extracellular matrix, is located between the synovial cavity and the stroma. In normal synovium, the lining layer is two to three cells deep, although intra-articular fat pads usually are covered by only a single layer of synovial cells, and ligaments and tendons are covered by synovial cells that are widely separated. At some sites, lining cells are absent, and extracellular connective tissue constitutes the lining layer.¹²⁷ Such “bare areas” become increasingly frequent with advancing age.¹²⁸ Although the synovial lining is often referred to as the *synovial membrane*, the term *membrane* is more correctly reserved for endothelial and epithelial tissues that have basement membranes, tight

intercellular junctions, and desmosomes. Instead, synovial lining cells lie loosely in a bed of hyaluronate interspersed with collagen fibrils. This is the macromolecular sieve that imparts the semipermeable nature of the synovium. The absence of any true basement membrane is a major determinant of joint physiology.

Early electron microscopic studies characterized lining cells as macrophage-derived type A synoviocytes and fibroblast-derived type B synoviocytes.¹²⁹ High UDPGD activity and CD55 are used to distinguish type B synovial cells, whereas nonspecific esterase and CD68 typify type A cells.^{130,131} Normal synovium is lined predominantly by fibroblast-like cells, whereas macrophage-like cells account for only 10% to 20% of lining cells (see Figure 1-6).

Type A, macrophage-like synovial cells contain vacuoles, a prominent Golgi apparatus, and filopodia, but they have little rough endoplasmic reticulum. These cells express numerous cell surface markers of the monocyte-macrophage lineage, including CD11b, CD68, CD14, CD163, and the immunoglobulin (Ig)G Fc receptor, FcγRIIIa.¹⁰⁵ Synovial intimal macrophages are phagocytic and may provide a mechanism by which particulate matter can be cleared from the normal joint cavity. Similar to other tissue macrophages, these cells have little capacity to proliferate and are likely localized to the joint during development. The op/op osteopetrotic mouse that is deficient in macrophages because of an absence of macrophage colony-stimulating factor also lacks synovial macrophages.¹³² This finding provides further evidence that type A synovial cells are of a common lineage with other tissue macrophages. Although they represent only a small percentage of cells in the normal synovium, macrophages are recruited from the circulation during synovial inflammation, in part from subchondral bone marrow through vascular channels near the enthesis.

The type B, fibroblast-like synovial cell contains fewer vacuoles and filopodia than type A cells and has abundant protein-synthetic organelles. Similar to other fibroblasts, lining cells express the collagen synthesis enzyme and synthesize extracellular matrix components, including collagens, sulfated proteoglycans, fibronectin, fibrillin-1, and

tenascin.^{105,133} They have the potential to proliferate, although proliferation markers are rarely seen in normal synovium.¹³⁴ In contrast to stromal fibroblasts, synovial intimal fibroblasts express UDPGD and synthesize hyaluronan, an important constituent of synovial fluid.¹⁰⁵ They also synthesize lubricin, which, together with hyaluronan, is necessary for the low-friction interaction of cartilage surfaces in the diarthrodial joint. Synovial lining cells bear abundant membrane peptidases on their surface, capable of degrading a wide range of regulatory peptides, such as substance P and angiotensin II.¹³⁵ These enzymes may be important in limiting the diffusion of these potent peptide mediators away from the immediate vicinity of their site of release and action.

Normal synovial lining cells also express a rich array of adhesion molecules, including CD44, the principal receptor for hyaluronan; vascular cell adhesion molecule (VCAM)-1; and intercellular adhesion molecule (ICAM)-1.^{105,136-138} They are essential for cellular attachment to specific matrix components in the synovial lining region, preventing loss into the synovial cavity of cells subjected to deformation and shear stresses during joint movement. Adhesion molecules such as VCAM-1 and ICAM-1 potentially are involved in the recruitment of inflammatory cells during the evolution of arthritis. Cadherins mediate cell-cell adhesion between adjacent cells of the same type. The identification of cadherin-11 as a key adhesion molecule that regulates formation of the synovial lining during development and the synoviocyte function postnatally has provided the opportunity to examine its role in inflammatory joint disease.¹⁰⁶ Recent studies have shown that cadherin-11 is highly expressed in fibroblast-like cells at the pannus-cartilage interface in rheumatoid synovium, where it plays a role in the invasive properties of the synovial fibroblasts¹³⁹; treatment with a cadherin-11 antibody or a cadherin-11 fusion protein has been shown to reduce synovial inflammation and cartilage erosion in an animal model of arthritis.¹⁰⁷

Synovial Vasculature

The subintimal synovium contains blood vessels, which provide the blood flow required for solute and gas exchange in the synovium itself and for generation of synovial fluid.¹²¹ The avascular articular cartilage also depends on nutrition in the synovial fluid, derived from the synovial vasculature. The vascularized synovium behaves similar to an endocrine organ, generating factors that regulate synoviocyte function and serving as a selective gateway that recruits cells from the circulation during stress and inflammation.¹⁴⁰ Finally, synovial blood flow plays an important role in regulating intra-articular temperature.

The synovial vasculature can be divided, on morphologic and functional grounds, into arterioles, capillaries, and venules. In addition, lymphatics accompany arterioles and larger venules.^{105,121} Arterial and venous networks of the joint are complex and are characterized by arteriovenous anastomoses that communicate freely with blood vessels in periosteum and periarticular bone. As large synovial arteries enter the deep layers of the synovium near the capsule, they give off branches, which bifurcate again to form *microvascular units* in the subsynovial layers. The synovial lining

region, the surfaces of intra-articular ligaments, and the entheses (in the angle of ligamentous insertions into bone) are particularly well vascularized.¹²¹

The distribution of synovial vessels, which were formed largely as a result of vasculogenesis during development of the joint, displays considerable plasticity. Vasculogenesis is a dynamic process that depends on cellular interactions with regulatory factors and the extracellular matrix that are also important in angiogenesis. In inflammatory arthritis, the density of blood vessels decreases relative to the growing synovial mass, creating a hypoxic and acidotic environment.^{141,142} Angiogenic factors such as VEGF, acting via VEGF receptors 1 and 2 (Flt-1 and Flk-1), and basic FGF promote proliferation and migration of endothelial cells—a process that is facilitated by matrix-degrading enzymes and adhesion molecules such as integrin $\alpha v \beta 3$ and E-selectin, expressed by activated endothelial cells.¹⁴³⁻¹⁴⁵ Vessel maturation is facilitated by angiopoietin-1 acting via the Tie-2 receptor. Angiogenic molecules are restricted to the capillary epithelium in normal synovium, but their levels are elevated in inflamed synovium in perivascular sites and areas remote from vessels.^{146,147}

Regulation of Synovial Blood Flow

Synovial blood flow is regulated by intrinsic (autocrine and paracrine) and extrinsic (neural and humoral) systems. Locally generated factors, such as the peptide vasoconstrictors angiotensin II and endothelin-1, act on adjacent arteriolar smooth muscle to regulate regional vascular tone.¹²¹ Normal synovial arterioles are richly innervated by sympathetic nerves containing vasoconstrictors, such as norepinephrine and neuropeptide Y, and by “sensory” nerves that also play an efferent vasodilatory role by releasing neuropeptides, such as substance P and calcitonin gene-related peptide.^{148,149} Arterioles regulate regional blood flow. Capillaries and postcapillary venules are sites of fluid and cellular exchange. Correspondingly, regulatory systems are differentially distributed along the vascular axis. Angiotensin-converting enzyme, which generates angiotensin II, is localized predominantly in arteriolar and capillary endothelia and is decreased during inflammation.¹⁵⁰ Specific receptors for angiotensin II and for substance P are abundant on synovial capillaries, with lower densities on adjacent arterioles. Dipeptidyl peptidase IV, a peptide-degrading enzyme, is specifically localized to the cell membranes of venular endothelium. The synovial vasculature not only is functionally compartmentalized from the surrounding stroma, but is also highly specialized along its arteriovenous axis. Other unique characteristics of the normal synovial vasculature include the presence of inducible nitric oxidase synthase-independent 3-nitrotyrosine, a reaction product of peroxynitrite,¹⁵¹ and localization of the synoviocyte-derived CXCL12 chemokine on heparan sulfate receptors on endothelial cells,¹⁵² suggesting physiologic roles for these molecules in normal vascular function.

Joint Innervation

Dissection studies have shown that each joint has a dual nerve supply, consisting of specific articular nerves that penetrate the capsule as independent branches of adjacent

peripheral nerves and articular branches that arise from related muscle nerves. The definition of joint position and the detection of joint motion are monitored separately and through a combination of multiple inputs from different receptors in varied systems. Nerve endings in muscle and skin and in the joint capsule mediate the sensation of joint position and movement.^{153,154} Normal joints have afferent (sensory) and efferent (motor) innervations. Fast-conducting, myelinated A fibers innervating the joint capsule are important for proprioception and detection of joint movement; slow-conducting, unmyelinated C fibers transmit diffuse pain sensation and regulate synovial microvascular function.

Normal synovium is richly innervated by fine, unmyelinated nerve fibers that follow the courses of blood vessels and extend into the synovial lining layers.¹⁴⁸ These nerve fibers do not have specialized endings and are slow-conducting fibers; they may transmit diffuse, burning, or aching pain sensation. Sympathetic nerve fibers surround blood vessels, particularly in the deeper regions of normal synovium. They contain and release classic neurotransmitters, such as norepinephrine, and neuropeptides that constrict synovial blood vessels. Neuropeptides that are markers of sensory nerves include substance P, calcitonin gene-related peptide, neuropeptide Y, and vasoactive intestinal peptide.^{148,155-157}

Afferent nerves containing substance P also have an efferent role in the synovium. Substance P is released from peripheral nerve terminals into the joint, and specific, G protein-coupled receptors for substance P are localized to microvascular endothelium in normal synovium. Abnormalities of articular innervation that are associated with inflammatory arthritis may contribute to the failure of synovial inflammation to resolve.^{148,158} Excessive local neuropeptide release may result in loss of nerve fibers owing to neuropeptide depletion. Synovial tissue proliferation without concomitant growth of new nerve fibers may lead to an apparent partial denervation of synovium.^{148,158} Studies in patients suggest that free nerve endings containing substance P may modulate inflammation and the pain pathway in osteoarthritis.¹⁵⁹ Afferent nerve fibers from the joint play an important role in the reflex inhibition of muscle contraction. Trophic factors generated by motor neurons, such as the neuropeptide calcitonin gene-related peptide, are important in maintaining muscle bulk and a functional neuromuscular junction.¹⁶⁰ Decreases in motor neuron trophic support during articular inflammation probably contribute to muscle wasting.

Mechanisms of joint pain have been reviewed in detail.^{161,162} In a noninflamed joint, most sensory nerve fibers do not respond to movement within the normal range; these are referred to as *silent nociceptors*. In an acutely inflamed joint, however, these nerve fibers become sensitized by mediators, such as bradykinin, neurokinin 1, and prostaglandins (peripheral sensitization), such that normal movements induce pain. Pain sensation is upregulated or downregulated further in the central nervous system, at the level of the spinal cord, and in the brain by central sensitization and *gating* of nociceptive input. Although the normal joint may respond predictably to painful stimuli, poor correlation has been noted between apparent joint disease and perceived pain in chronic arthritis. Pain associated with joint movements within the normal range is a characteristic

symptom described by patients with chronically inflamed joints caused by rheumatoid arthritis. Chronically inflamed joints may not be painful at rest, however, unless acutely inflamed.¹⁶³

Tendons

Tendons are functional and anatomic bridges between muscle and bone.^{164,165} They focus the force of a large mass of muscle into a localized area on bone and, by splitting to form numerous insertions, may distribute the force of a single muscle to different bones. Tendons are formed of longitudinally arranged collagen fibrils embedded in an organized, hydrated proteoglycan matrix with blood vessels, lymphatics, and fibroblasts.¹⁶⁶ Cross-links between adjacent collagen chains or molecules contribute to the tensile strength of the tendon.^{167,168} Tendon collagen fibrillogenesis is initiated during early development through a highly ordered process of alignment involving the actin cytoskeleton and cadherin-11.^{169,170} Many tendons, particularly tendons with a large range of motion, run through vascularized, discontinuous sheaths of collagen lined with mesenchymal cells resembling synovium. Gliding of tendons through their sheaths is enhanced by hyaluronic acid produced by the lining cells. Tendon movement is essential for the embryogenesis and maintenance of tendons and their sheaths. Degenerative changes appear in tendons, and fibrous adhesions are formed between tendons and sheaths when inflammation or surgical incision is followed by long periods of immobilization.¹⁷¹ At the myotendinous junction, recesses between muscle cell processes are filled with collagen fibrils, which blend into the tendon. At its other end, collagen fibers of the tendon typically blend into fibrocartilage or mineralize, and merge into bone through a fibrocartilaginous transition zone termed the *enthesis*, or insertion site.¹⁷²

Tendon fibroblasts synthesize and secrete collagens, proteoglycans, and other matrix components, such as fibronectin and tenascin C, and MMPs and their inhibitors, which can contribute to the breakdown and repair of tendon components.^{166,173-176} Collagen fibrils in tendon are composed primarily of type I collagen with some type III collagen, but regional differences in the distribution of other matrix components have been noted. The compressed region contains the small proteoglycans—biglycan, decorin, fibromodulin, and lumican—and a large proteoglycan—versican.^{177,178} Major components in the tensile region of the tendon are decorin, microfibrillar type VI collagen, fibromodulin, and the proline and arginine-rich end leucine-rich repeat protein (PRELP). The presence of cartilage oligomeric matrix protein, aggrecan, biglycan, and collagen types II, IX, and XI is indicative of fibrocartilage.^{179,180} The collagen fiber orientation at the tendon-to-bone enthesis is important for maintaining microarchitecture by reducing stress concentrations and shielding the outward splay of insertion from the highest stresses.¹⁸¹ Understanding the structure has implications for tendon repair because motion between a tendon graft and a bone tunnel may impair early graft incorporation, leading to tunnel widening secondary to bone resorption.¹⁸²

Failure of the muscle-tendon apparatus is rare, but when it does occur, it is secondary to enormous, quickly generated

forces across a joint and usually occurs near the tendon insertion into bone.^{183,184} Factors that may predispose to tendon failure consist of aging processes, including loss of extracellular water and an increase in intermolecular cross-links of collagen; tendon ischemia; iatrogenic factors, including injection of glucocorticoids; and deposition of calcium hydroxyapatite crystals within the collagen bundles. Alterations in collagen fibril composition and structure are associated with tendon degeneration during aging and may predispose to osteoarthritis.^{179,185} Evidence indicates that BMPs promote tendon repair if osteogenic signaling is impaired.¹⁸⁶

Ligaments

Ligaments provide a stabilizing bridge between bones, permitting a limited range of movement.¹⁸⁷ The ligaments often are recognized only as hypertrophied components of the fibrous joint capsule and are structurally similar to tendons.¹⁸⁸ Although the fibers are oriented parallel to the longitudinal axis of both tissues,¹⁶⁴ the collagen fibrils in ligaments are nonparallel and arranged in fibers that are oriented roughly along the long axis in a wavy, undulating pattern, or *crimp*, which can straighten in response to load. Some ligaments have a higher ratio of elastin to collagen (1:4) than tendons (1:50), which permits a greater degree of stretch. Ligaments also have larger quantities of reducible cross-links, more type III collagen, slightly less total collagen, and more glycosaminoglycans compared with tendons. The cells in ligaments seem to be more metabolically active than those in tendons and have more plump cellular nuclei and higher DNA content.

During postnatal growth, the development of ligament attachment zones involves changes in the ratios and distribution of collagen types I, III, and V and the synthesis of type II collagen and proteoglycans by fibrochondrocytes that develop from ligament cells at the attachment zone.^{189,190} Attachment zones are believed to permit gradual transmission of the tensile force between ligament and bone.

Ligaments play a major role in the passive stabilization of joints, aided by the capsule and, when present, menisci. In the knee, the collateral and cruciate ligaments provide stability when there is little or no load on the joint. As compressive load increases, the contribution to stability from the joint surfaces themselves and the surrounding musculature increases as well. Injured ligaments generally heal, and structural integrity is restored by contracture of the healing ligament so that it can act again as a stabilizer of the joint.¹⁹¹

Bursae

The many bursae in the human body facilitate gliding of one tissue over another, much as a tendon sheath facilitates movement of its tendon. Bursae are closed sacs, lined sparsely with mesenchymal cells similar to synovial cells, but they are generally less well vascularized than synovium. Most bursae differentiate concurrently with synovial joints during embryogenesis. During life, however, trauma or inflammation may lead to the development of new bursae, hypertrophy of previously existing ones, or communication

between deep bursae and joints. In patients with rheumatoid arthritis, communications may exist between the subacromial bursae and the glenohumeral joint, between the gastrocnemius or semimembranosus bursae and the knee joint, and between the iliopsoas bursa and the hip joint. It is unusual, however, for subcutaneous bursae, such as the prepatellar bursa or olecranon bursa, to develop communication with the underlying joint.¹⁹²

Menisci

The meniscus, a fibrocartilaginous, wedge-shaped structure, is best developed in the knee, but also is found in the acromioclavicular and sternoclavicular joints, the ulnocarpal joint, and the temporomandibular joint.^{193,194} Until recently, menisci were thought to have little function and a quiescent metabolism with no capability of repair, although early observations indicated that removal of menisci from the knee may lead to premature arthritic changes in the joint.¹⁹⁵ Evidence from an arthroscopic study of patients with anterior cruciate ligament insufficiency indicates that the pathology of the medial meniscus correlates with that of the medial femoral cartilage.¹⁹⁶ The meniscus is now considered to be an integral component of the knee joint that has important functions in joint stability, load distribution, shock absorption, and lubrication.^{193,194}

The microanatomy of the meniscus is complex and age dependent.¹⁹⁷ The characteristic shape of the lateral and medial menisci is achieved early in prenatal development. At that time, the menisci are cellular and highly vascularized; with maturation, vascularity decreases progressively from the central margin to the peripheral margin. After skeletal maturity, the peripheral 10% to 30% of the meniscus remains highly vascularized by a circumferential capillary plexus and is well innervated.¹⁹⁸ Tears in this vascularized peripheral zone may undergo repair and remodeling.¹⁹⁹ The central portion of the mature meniscus is an avascular fibrocartilage, however, without nerves or lymphatics, consisting of cells surrounded by an abundant extracellular matrix of collagens, chondroitin sulfate, dermatan sulfate, and hyaluronic acid. Tears in this central zone heal poorly, if at all.

Collagen constitutes 60% to 70% of the dry weight of the meniscus and is mostly type I collagen, with lesser amounts of types III, V, and VI. A small quantity of cartilage-specific type II collagen is localized to the inner, avascular portion of the meniscus. Collagen fibers in the periphery are mostly circumferentially oriented, with radial fibers extending toward the central portion.²⁰⁰⁻²⁰³ Elastin content is around 0.6%, and proteoglycan content is around 2% to 3% dry weight. Aggrecan and decorin are the major proteoglycans in the adult meniscus.^{204,205} Decorin is the predominant proteoglycan synthesized in the meniscus from young individuals, whereas the relative proportion of aggrecan synthesis increases with age. Although the capacity of the meniscus to synthesize sulfated proteoglycans decreases after the teenage years, age-related increases in expression of decorin and aggrecan mRNA suggest that the resident cells are able to respond quickly to alterations in the biomechanical environment.²⁰⁶

The meniscus was defined originally as a fibrocartilage, based on the rounded or oval shape of most of the cells and

the fibrous microscopic appearance of the extracellular matrix.²⁰⁷ Based on molecular and spatial criteria, three distinct populations of cells are recognized in the meniscus of the knee joint²⁰¹:

1. The fibrochondrocyte is the most abundant cell in the middle and inner meniscus, synthesizing primarily type I collagen and relatively small amounts of type II and III collagen. It is round or oval in shape and has a pericellular filamentous matrix containing type VI collagen.
2. The fibroblast-like cells lack a pericellular matrix and are located in the outer portion of the meniscus. They are distinguished by long, thin, branching cytoplasmic projections that stain for vimentin. They make contact with other cells in different regions via connexin 43-containing gap junctions. The presence of two centrosomes, one associated with a primary cilium, suggests a sensory, rather than motile, function that could enable the cells to respond to circumferential tensile loads, rather than compressive loads.²⁰⁸
3. The superficial zone cells have a characteristic fusiform shape with no cytoplasmic projections. Occasional staining of these cells in the uninjured meniscus with α -actin and their migration into surrounding wound sites suggest that they are specialized progenitor cells that may participate in a remodeling response in the meniscus and surrounding tissues.^{209, 210}

MATURE ARTICULAR CARTILAGE

Articular cartilage is a specialized connective tissue that covers the weight-bearing surfaces of diarthrodial joints.^{119,211} The principal functions of cartilage layers covering bone ends are to permit low-friction, high-velocity movement between bones, to absorb transmitted forces associated with locomotion, and to contribute to joint stability. Lubrication by synovial fluid provides frictionless movement of the articulating cartilage surfaces. Chondrocytes (see Chapter 3) are the single cellular components of adult hyaline articular cartilage and are responsible for synthesizing and maintaining the highly specialized cartilage matrix macromolecules. The cartilage extracellular matrix is composed of an extensive network of collagen fibrils, which confers tensile strength, and an interlocking mesh of proteoglycans, which provides compressive stiffness through the ability to absorb and extrude water. Numerous other noncollagenous proteins also contribute to the unique properties of cartilage (Table 1-1). Histologically, the tissue appears to be fairly homogeneous and is clearly distinguished from calcified cartilage and underlying subchondral bone (Figure 1-7). The organization of articular cartilage and the structure-function relationships of cartilage matrix components are described in Chapter 3.

Subchondral Bone Interactions with Articular Cartilage

Subchondral bone is not a homogeneous tissue; it consists of a layer of compact cortical bone and an underlying system of cancellous bone organized into a trabecular network.^{212,213} The subchondral bone is separated from the overlying articular cartilage by a thin zone of calcified cartilage. The

*The collagens, proteoglycans, and other noncollagenous proteins in the cartilage matrix are synthesized by chondrocytes at different stages during development and growth of cartilage. In mature articular cartilage, proteoglycans and other noncollagen proteins are turned over slowly, whereas the collagen network is stable unless exposed to proteolytic cleavage. Proteins that are associated with chondrocyte cell membranes also are listed because they permit specific interactions with extracellular matrix proteins. The specific structure-function relationships are discussed in Chapter 3 and are described in Table 3-1.

so-called tidemark defines the transition zone between articular and calcified cartilage. This complex biocomposite of bone and calcified cartilage provides an optimal system for distributing loads that are transmitted from the weight-bearing surfaces lined by hyaline articular cartilage. Although the tidemark was originally believed to form a barrier to fluid flow, evidence suggests that biologically active molecules can transit this zone, providing a mechanism by which products produced by chondrocytes or bone cells can influence the activity of the other cell type.²¹⁴

Figure 1-7 Representative sections of normal human adult articular cartilage show nearly the same field in plain (A) and polarized (B) light. Note the clear demarcation of the articular cartilage from the calcified cartilage below the tidemark and the underlying subchondral bone. (Hematoxylin-eosin stain; original magnification $\times 60$.) (Courtesy Edward F. DiCarlo, MD, Pathology Department, Hospital for Special Surgery, New York.)

Under physiologic conditions, the composition and structural organization of subchondral bone and calcified cartilage are optimally adapted to transfer loads, but multiple conditions can lead to changes in the structural and functional properties of these tissues. For example, with advancing age, the zone of calcified cartilage may expand and advance into the deep zones of the overlying articular cartilage, producing thinning of the cartilage layer and alterations in load transfer and fibrillation and disruption of the cartilage surface.²¹⁵

Maintenance of the structural and functional integrity of articular cartilage and subchondral bone under physiologic loading provides evidence of the unique and intimate interaction of these tissues, but there remains controversy regarding the relationship between them in the pathogenesis of osteoarthritis.²¹⁶ Radin and Rose²¹⁷ proposed that the initiation of early alterations in articular cartilage is caused by an increase in subchondral bone stiffness that adversely affects the function of articular chondrocytes, leading to deterioration in the properties of the articular cartilage and susceptibility to mechanical disruption. Alternatively, it has been proposed that changes in subchondral bone stiffness may be secondary to cartilage deterioration.²¹⁸⁻²²⁰ The alterations in subchondral bone and cartilage that accompany the osteoarthritis process are not restricted to these tissues, but also affect the zone of calcified cartilage, where evidence reveals vascular invasion, advancement of the calcified cartilage, and duplication of the tidemark, which contributes further to a decrease in articular cartilage thickness.²²¹ A more recent study showed that angiogenesis in the osteochondral junction is independent of synovial angiogenesis and synovitis, but is associated with cartilage changes and clinical disease activity.²²² These structural alterations in

the articular cartilage and periarticular bone may lead to modification of the contours of adjacent articulating surfaces, further contributing to the adverse biomechanical environment.^{217,223-225}

Analyses of periarticular bone in patients with osteoarthritis reveal that the structural and functional properties of subchondral cortical and trabecular bone are dependent on the stage of osteoarthritis progression.²²⁶ Several studies have investigated therapies that target bone remodeling to prevent these changes. Examples include the use of calcitonin,^{227,228} bisphosphonates,²²⁹ and estrogen.²³⁰ To date, no study has been performed in patients with osteoarthritis to investigate the efficacy of targeting receptor activator of nuclear factor κ B (NF κ B) ligand (RANKL), which mediates osteoclast differentiation and activity, and its receptor RANK, a member of the tumor necrosis factor receptor family. RANK is expressed in adult articular chondrocytes, but exogenous RANKL does not activate NF κ B nor stimulate the production of collagenase or nitric oxide.²³¹ Inhibition of RANKL expression does not block cartilage destruction in inflammatory models,²³² although RANKL may have indirect effects on cartilage through its protective effect on bone.²³³

SYNOVIAL FLUID AND NUTRITION OF JOINT STRUCTURES

The volume and composition of synovial fluid are determined by the properties of the synovium and its vasculature. Fluid in normal joints is present in small quantities (2.5 mL in the normal knee) sufficient to coat the synovial surface, but not to separate one surface from the other. Tendon

sheath fluid and synovial fluid are biochemically similar. Both are essential for the nutrition and lubrication of adjacent avascular structures, including tendon and articular cartilage, and for limiting adhesion formation and maintaining movement. Characterization and measurement of synovial fluid constituents have proved useful for the identification of locally generated regulatory factors, markers of cartilage turnover, and the metabolic status of the joint, and for assessment of the effects of therapy on cartilage homeostasis. Interpretation of such data requires, however, an understanding of the generation and clearance of synovial fluid and its various components.

Generation and Clearance of Synovial Fluid

Synovial fluid concentrations of a protein represent the net contributions of synovial blood flow, plasma concentration, microvascular permeability, and lymphatic removal and its production and consumption within the joint space. Synovial fluid is a mixture of a protein-rich ultrafiltrate of plasma and hyaluronan synthesized by synoviocytes. Generation of this ultrafiltrate depends on the difference between intra-capillary and intra-articular hydrostatic pressures and between colloid osmotic pressures of capillary plasma and synovial tissue fluid. Fenestrations, small pores covered by a thin membrane, in the synovial capillaries and the macromolecular sieve of hyaluronic acid facilitate rapid exchange of small molecules, such as glucose and lactate, assisted—in the case of glucose—by an active transport system.²³⁴ Proteins are present in synovial fluid at concentrations inversely proportional to molecular size, with synovial fluid albumin concentrations being about 45% of those in plasma (Figure 1-8).²³⁵ Concentrations of electrolytes and small molecules are equivalent to those in plasma.²³⁶

Synovial fluid is cleared through lymphatics in the synovium, assisted by joint movement. In contrast to ultrafiltration, lymphatic clearance of solutes is independent of molecular size. In addition, constituents of synovial fluid, such as regulatory peptides, may be degraded locally by enzymes, and low-molecular-weight metabolites may diffuse along concentration gradients into plasma. The kinetics of delivery and removal of a protein must be determined (e.g., using albumin as a reference solute) to assess the significance of its concentration in the joint.²³⁷

Hyaluronic acid is synthesized by fibroblast-like synovial lining cells, and it appears in high concentrations in synovial fluid, at around 3 g/L, compared with a plasma concentration of 30 µg/L. Lubricin, a glycoprotein that assists articular lubrication, is another constituent of synovial fluid that is generated by the lining cells. It is now believed that hyaluronan functions in fluid-film lubrication, whereas lubricin is the true boundary lubricant in synovial fluid (see following). Because the volume of synovial fluid is determined by the amount of hyaluronan, water retention seems to be the major function of this large molecule.^{234,238}

Despite the absence of a basement membrane, synovial fluid does not mix freely with extracellular synovial tissue fluid. Hyaluronan may trap molecules within the synovial cavity by acting as a filtration screen on the surface of the synovial lining, resisting the movement of synovial fluid out from the joint space.²³⁸ Synovial fluid and its constituent proteins have a rapid turnover time (around 1 hour in

Figure 1-8 Ratio of the concentration of proteins in synovial fluid to that found in serum, plotted as a function of molecular weight. Larger proteins are selectively excluded from normal synovial fluid, but this macromolecular sieve is less effective in diseased synovium. Conc., concentration; RA, rheumatoid arthritis; S, serum; SF, synovial fluid. (From Kushner I, Somerville JA: *Permeability of human synovial membrane to plasma proteins*, *Arthritis Rheum* 14:560, 1971. Reprinted with permission of the American College of Rheumatology.)

normal knees), and equilibrium is not usually reached among all parts of the joint. Tissue fluid around fenestrated endothelium reflects plasma ultrafiltrate most closely, with a low content of hyaluronate compared with synovial fluid. Alternatively, locally generated or released peptides, such as endothelin and substance P, may attain much higher perivascular concentrations than those measured in synovial fluid. The turnover time for hyaluronan in the normal joint (13 hours) is an order of magnitude slower, however, than that for small solutes and proteins. Association with hyaluronan may result in trapping of solutes within synovial fluid.²³⁹

In normal joints, intra-articular pressures are slightly sub-atmospheric at rest (0 to −5 mm Hg).²⁴⁰ During exercise, hydrostatic pressure in the normal joint may decrease further. Resting intra-articular pressures in rheumatoid joints are around 20 mm Hg, whereas during isometric exercise, they may increase to greater than 100 mm Hg—well above capillary perfusion pressure and, at times, above arterial pressure. Repeated mechanical stresses can interrupt synovial perfusion during joint movement, particularly in the presence of a synovial effusion.

Synovial Fluid as an Indicator of Joint Function

In the absence of a basement membrane separating synovium or cartilage from synovial fluid, measurements made on synovial fluid may reflect the activity of these structures. A

wide range of regulatory factors and products of synovocyte metabolism and cartilage breakdown may be generated locally within the joint, resulting in marked differences between the composition of synovial fluid and that of plasma ultrafiltrate. Because there is little capacity for the selective concentration of solutes in synovial fluid, solutes present at higher concentrations than in plasma are probably synthesized locally. It is necessary to know the local clearance rate, however, to determine whether solutes present in synovial fluid at lower concentrations than in plasma are generated locally.²³⁶ Although microvascular permeability to protein in highly inflamed rheumatoid joints is more than twice that in osteoarthritic joints, synovial fluid protein concentrations vary little between the two joint diseases²⁴¹ because enhanced entry of proteins through the microvasculature is largely offset by the increased lymphatic clearance.²⁴² Because clearance rates from synovial fluid may be slower than those from plasma, however, synovial fluid levels of drugs or urate may remain elevated after plasma levels have declined.²³⁴

Comparisons of synovial fluid constituents between disease groups are often limited by the sparseness of data on normal synovial fluid as a result of difficulties in its collection. Extrapolation from synovial fluid concentrations to local synthetic rates is complicated further by variations in clearance rates and in synovial fluid volume. Plasma proteins are less effectively filtered in inflamed synovium, perhaps because of the increased size of endothelial cell fenestrations, or because interstitial hyaluronate-protein complexes are fragmented by enzymes associated with the inflammatory process.²³⁵ Concentrations of proteins, such as α_2 -macroglobulin (the principal proteinase inhibitor of plasma), fibrinogen, and IgM, are elevated in inflammatory synovial fluids (see Figure 1-8), as are associated protein-bound cations. Membrane peptidases may limit the diffusion of regulatory peptides from their sites of release into synovial fluid. In inflammatory arthritis, fibrin deposits may retard flow between tissue and liquid phases. Cautious interpretation of synovial fluid analysis has important implications in understanding how to use data on biomarkers of cartilage damage and repair in rheumatoid arthritis and osteoarthritis (see Chapter 53).

Recently, Gobeze and co-workers²⁴³ have utilized high-throughput mass spectroscopy-based proteomic analysis to define the protein expression profiles of high-abundance synovial fluid proteins in healthy subjects and patients with early and late osteoarthritis. They identified 18 proteins that were significantly differentially expressed between osteoarthritic and control groups. Although all of the differentially expressed proteins are present in the blood and could therefore enter the joint through alterations in vascular permeability associated with the disease state, these molecules are also products of synovial cells and chondrocytes, suggesting that they could be locally produced within the joint. Proteins associated with oxidative damage and activation of mitogen-activated protein kinases were among the high-abundance molecules in osteoarthritis synovial fluids. Members of the proinflammatory complement cascade were also identified in the synovial fluid. Of interest, these molecules have been implicated in the pathophysiology of both osteoarthritis and rheumatoid arthritis.

Lubrication and Nutrition of the Articular Cartilage

Lubrication

Synovial fluid serves as a lubricant for articular cartilage and as a source of nutrition for the chondrocytes within. Lubrication is essential for protecting cartilage and other joint structures from friction and shear stresses associated with movement under loading. Two basic categories of joint lubrication are known. In fluid-film lubrication, cartilage surfaces are separated by an incompressible fluid film; hyaluronan functions as the lubricant. In boundary lubrication, specialized molecules attached to the cartilage surface permit surface-to-surface contact, while decreasing the coefficient of friction.

During loading, a noncompressible fluid film trapped between opposing cartilage surfaces prevents the surfaces from touching. Irregularities in the cartilage surface and its deformation during compression may augment this trapping of fluid. This stable film is approximately 0.1 μm thick in the normal human hip joint, but it can be much thinner in the presence of inflammatory synovial fluids or with increased cartilage porosity.^{244,245}

Lubricin is the major boundary lubricant in the human joint.²⁴⁶ It is a glycoprotein, also called *superficial zone protein* or *proteoglycan 4*, that is synthesized by synovial cells and chondrocytes.²⁴⁷⁻²⁵⁰ Recent studies have demonstrated that lubricin is also produced by meniscal and tendon cells.^{251,252} It has a molecular weight of 225,000, a length of 200 nm, and a diameter of 1 to 2 nm.²⁵³ Dipalmitoyl phosphatidylcholine, which constitutes 45% of the lipid in normal synovial fluid, acts together with lubricin as a boundary lubricant.²⁵⁴ More recent work indicates that lubricin functions as a phospholipid carrier via a mechanism that is common to all tissues.^{255,256} In cartilage, lipid composes 1% to 2% of the dry weight,²⁵⁷ and experimental treatment of cartilage surfaces with fat solvents impairs lubrication qualities.²⁵⁸

Nutrition

As observed by Hunter in 1743,²⁵⁹ normal adult articular cartilage contains no blood vessels. Vascularization of cartilage would be expected to alter its mechanical properties. Blood flow would be repeatedly occluded during weight bearing and exercise, with reactive oxygen species generated during reperfusion, resulting in repeated damage to cartilage matrix and chondrocytes. Chondrocytes synthesize specific inhibitors of angiogenesis that maintain articular cartilage as an avascular tissue.²⁶⁰⁻²⁶² As a result of the lack of adjacent blood vessels, the chondrocyte normally lives in an hypoxic and acidotic environment, with extracellular fluid pH values around 7.1 to 7.2,²⁶³ and it uses anaerobic glycolysis for energy production.^{264,265} High lactate levels in normal synovial fluid, compared with paired plasma measurements, partially reflect this anaerobic metabolism.²⁶⁵ There are two sources of nutrients for articular cartilage: synovial fluid and subchondral blood vessels.

The synovial fluid and, indirectly, the synovial lining, through which synovial fluid is generated, are the major sources of nutrients for articular cartilage. Nutrients may

enter cartilage from synovial fluid by diffusion or by mass transport of fluid during compression-relaxation cycles.²⁶⁶ Molecules as large as hemoglobin (65 kD) can diffuse through normal articular cartilage,²⁶⁷ and the solutes needed for cellular metabolism are much smaller. Diffusion of uncharged small solutes, such as glucose, is not impaired in matrices containing large quantities of glycosaminoglycans, and the diffusivity of small molecules through hyaluronate is enhanced.^{268,269}

Intermittent compression may serve as a pump mechanism for solute exchange in cartilage. The concept has arisen from observations that joint immobilization or dislocation leads to degenerative changes. In contrast, exercise increases solute penetration into cartilage in experimental systems.²⁶⁷ During weight bearing, fluid escapes from the load-bearing region by flow to other cartilage sites. When the load is removed, cartilage re-expands and draws back fluid, exchanging nutrients with waste materials.²⁷⁰

In a growing child, the deeper layers of cartilage are vascularized, such that blood vessels penetrate between columns of chondrocytes in the growth plate. It is likely that nutrients diffuse from these tiny end capillaries through the matrix to chondrocytes. Diffusion from subchondral blood vessels is not considered a major route for the nutrition of normal adult articular cartilage because of the barrier provided by its densely calcified lower layer. Nonetheless, partial defects may normally exist in this barrier,²⁷¹ and in arthritis, neovascularization of the deeper layers of articular cartilage may contribute to cartilage nutrition and to entry of inflammatory cells and cytokines.^{221,272} In aging and osteoarthritis, tidemark “duplication” may indicate communication between bone and cartilage.^{218,273} Experimental studies have indicated that cartilage lesions of chondromalacia may develop if the subchondral blood supply of the patella is compromised.²⁷⁴

SUMMARY AND CONCLUSION

Normal human synovial joints are complex structures that comprise interacting connective tissue elements that permit constrained and low-friction movement of adjacent bones. The development of synovial joints in the embryo is a highly ordered process involving complex cell-cell and cell-matrix interactions, leading to the formation of cartilage anlagen and interzone and joint cavitation. Understanding of the cellular interactions and molecular factors involved in cartilage morphogenesis and limb development has provided clues to understanding the functions of the synovium, articular cartilage, and associated structures in the mature joint.

The synovial joint is uniquely adapted to responding to environmental and mechanical demands. The synovial lining is composed of two to three cell layers, and no basement membrane separates the lining cells from underlying connective tissue. The synovium produces synovial fluid, which provides nutrition and lubrication to the avascular articular cartilage. Normal articular cartilage contains a single cell type, the articular chondrocyte, which is responsible for maintaining the integrity of the extracellular cartilage matrix. This matrix consists of a complex network of

collagens, proteoglycans, and other noncollagenous proteins, which provide tensile strength and compressive resistance. Proper distribution and relative composition of these proteins are required for the function of cartilage in protecting the subchondral bone from adverse environmental influences.

Maintenance of the unique composition and organization of each joint tissue is crucial for normal joint function, which is compromised in response to inflammation, biomechanical injury, and aging. Knowledge of normal structure-function relationships within joint tissues is essential for understanding the pathogenesis and consequences of joint disease.

Synovium

BARRY BRESNIHAN •
ADRIENNE M. FLANAGAN •
GARY S. FIRESTEIN

KEY POINTS

The synovium provides nutrients to cartilage and produces lubricants for the joint.

The intimal lining of the synovium includes macrophage-like and fibroblast-like synoviocytes.

The sublining in normal synovium contains scattered immune cells, fibroblasts, blood vessels, and fat cells.

Fibroblast-like synoviocytes in the intimal lining produce specialized enzymes that synthesize lubricants such as hyaluronic acid.

STRUCTURE

The synovium is a membranous structure that extends from the margins of articular cartilage and lines the capsule of diarthrodial joints, including the temporomandibular joint¹ and the facet joints of vertebral bodies (Figure 2-1).² The healthy synovium covers intra-articular tendons and ligaments, as well as fat pads, but not articular cartilage or meniscal tissue. Synovium also ensheathes tendons where they pass beneath ligamentous bands and bursas that cover areas of stress such as the patella and the olecranon. The synovial membrane is divided into general regions—the intima, or synovial lining, and the subintima, otherwise referred to as the *sublining*. The intima represents the interface between the cavity containing synovial fluid and the subintimal layer. No well-formed basement membrane separates the intima from the subintima. It is not a true lining, in contrast to the pleura or pericardium, because it lacks tight junctions, epithelial cells, and a well-formed basement membrane. The subintima is composed of fibrovascular connective tissue and merges with the densely collagenous fibrous joint capsule.

Synovial Lining Cells

The synovial intimal layer is composed of synovial lining cells (SLCs), which are arrayed on the luminal aspect of the joint cavity. SLCs, termed *synoviocytes*, are one to three cells deep, depending on the anatomic location, and extend 20 to 40 μm beneath the lining layer surface. The major and minor axes of SLCs measure 8 to 12 μm and 6 to 8 μm , respectively. The SLCs are not homogeneous and are conventionally divided into two major populations, namely, type A (macrophage-like) synoviocytes and type B (fibroblast-like) synoviocytes.³

Ultrastructure of Synovial Lining Cells

Transmission electron microscopic analysis shows that the intimal cells form a discontinuous layer, so that the subintimal matrix can directly contact the synovial fluid (Figure 2-2). The existence of two distinct cell types—type A and type B SLCs—was originally described by Barland and associates,⁴ and several lines of evidence, including animal models, detailed ultrastructural studies, and immunohistochemical analyses, indicate that these cells represent macrophages (type A SLCs) and fibroblasts (type B SLCs). Studies of SLC populations in a variety of species, including humans, have found that macrophages make up anywhere from 20% and fibroblast-like cells approximately 80% of the lining cell.^{5,6} The existence of the two cell types has been substantiated by similar findings in a wide variety of species, including hamsters, cats, dogs, guinea pigs, rabbits, mice, rats, and horses.⁶⁻¹⁴

Distinguishing different cell populations that form the synovial lining requires immunohistochemistry or transmission light microscopy. At an ultrastructural level, type A cells are characterized by a conspicuous Golgi apparatus, large vacuoles, and small vesicles, and they contain little rough endoplasmic reticulum, giving them a macrophage-like phenotype (Figure 2-3A and B). The plasma membrane of type A cells possesses numerous fine extensions, termed *filopodia*, which are characteristic of macrophages. Type A cells occasionally cluster at the tips of the synovial villi; this uneven distribution explains at least in part early reports that suggested type A cells were the predominant intimal cell type.^{4,8} However, the distribution is highly variable and can differ depending on the joint evaluated or even within an individual joint.

Type B SLCs have prominent cytoplasmic extensions that extend onto the surface of the synovial lining (Figure 2-3C and D).¹⁵ Frequent invaginations are seen along the plasma membrane; a large indented nucleus relative to the area of the surrounding cytoplasm is also a feature. Type B cells have abundant rough endoplasmic reticulum widely distributed in the cytoplasm, and the Golgi apparatus, vacuoles, and vesicles are generally inconspicuous, although some cells have small numbers of prominent vacuoles at their apical aspect. Type B SLCs are known to contain longitudinal bundles of different-sized filaments, supporting their classification as fibroblasts. Desmosomes and gap-like junctions have been described in rat, mouse, and rabbit synovium, but the existence of these structures in human SLCs has never been documented. Although occasional reports describe an intermediate synoviocyte phenotype, it is likely that these cells are functionally conventional type A or B cells.^{16,17}

Figure 2-1 The cartilage-synovium junction. Hyaline articular cartilage occupies the left half of this image, and fibrous capsule and synovial membrane occupy the right half. A sparse intimal lining layer with a fibrous subintima can be observed extending from the margin of the cartilage across the capsular surface to assume a more cellular intimal morphology with areolar subintima.

Immunohistochemical Profile of Synovial Cells

Synovial Macrophages. Synovial macrophages and fibroblasts express lineage-specific molecules, which can be detected by immunohistochemistry. Synovial macrophages express common hematopoietic antigen CD45 (Figure 2-4A); monocyte/macrophage receptors CD163 and CD97; and lysosomal enzymes CD68 (Figure 2-4B), neuron-specific esterase, and cathepsins B, L, and D. Cells expressing CD14, a molecule that acts as a co-receptor for the detection of bacterial lipopolysaccharide and expressed by circulating monocytes and monocytes newly recruited to tissue, are rarely seen in the healthy intimal layer, but small numbers are found close to venules in the subintima.¹⁸⁻²⁴

The Fcγ receptor, FcγRIII (CD16), expressed by Kupffer cells of the liver and type II alveolar macrophages of the lung, is expressed on a subpopulation of synovial macrophages.²⁵⁻²⁷ The synovial macrophage population also expresses the major histocompatibility complex (MHC) class II molecule, which plays an important role in the immune response. More recently, the macrophages, which are responsible for the removal of debris, blood, and

Figure 2-2 Transmission electron photomicrograph of synovial intimal lining cells. The cell on the left exhibits the dendritic appearance of a synovial intimal fibroblast (type B cell). Other overlying fibroblast dendrites can be observed. Intercellular gaps allow the synovial fluid to be in direct contact with the synovial matrix.

particulate material from the joint cavity and possess antigen processing properties, have been found to express the complement-related protein, Z39Ig, a cell surface receptor and immunoglobulin superfamily member involved in the induction of human leukocyte antigen (HLA)-DR and in implicated phagocytosis and antigen-mediated immune responses.²⁸⁻³⁰

Expression of the β2 integrin chains—CD18, CD11a, CD11b, and CD11c—varies; CD11a and CD11c may be absent or weakly expressed on a few lining cells.^{31,32} Osteoclasts, which are tartrate resistant and acid phosphatase positive and express the α_vβ₃ vitronectin and calcitonin receptors, do not appear in the normal synovium.

Synovial Intimal Fibroblasts. Synovial intimal and subintimal fibroblasts are indistinguishable by light microscopy. They generally are considered to be closely related in terms of cell lineage, but because of their different microenvironments, they do not always share the same phenotype. They possess prominent synthetic capacity and produce the essential joint lubricants hyaluronic acid (HA) and lubricin.³³ Intimal fibroblasts express uridine diphosphoglucose dehydrogenase (UDPGD), an enzyme involved in HA synthesis that is a relatively specific marker for this cell type. UDPGD converts UDP-glucose to UDP-glucuronate, one of the two substrates required by HA synthase for assembly of the HA polymer.³⁴ CD44, the nonintegrin receptor for HA, is expressed by all SLCs.^{32,35,36}

Synovial fibroblasts also synthesize normal matrix components, including fibronectin, laminin, collagens, proteoglycans, lubricin, and other identified and unidentified proteins. They have the capacity to produce large quantities of metalloproteinases, metalloproteinase inhibitors, prostaglandins, and cytokines. This capacity must provide essential biologic advantages, but the complex physiologic mechanisms relevant to normal function are incompletely delineated. Expression of selected adhesion molecules on synovial fibroblasts probably facilitates the trafficking of some cell populations, such as neutrophils, into the synovial fluid, and retention of others, such as mononuclear leukocytes, in the synovial tissue. Expression of metalloproteinases, cytokines, adhesion molecules, and other cell surface molecules is strikingly increased in inflammatory states.

Specialized intimal fibroblasts express many other molecules that might be expressed by the intimal macrophage population or by most subintimal fibroblasts, including decay-accelerating factor (CD55); vascular cell adhesion molecule-1^{33,37-40}; and cadherin-11.^{41,42} PGP.95, a neuronal marker, might be specific for type B synoviocytes in some species.⁴³ Decay-accelerating factor, also expressed on many other cells (most notably erythrocytes) as well as bone marrow cells, interacts with CD97, a glycoprotein that is present on the surface of activated leukocytes, including intimal macrophages, and is thought to be involved in signaling processes early after leukocyte activation.^{44,45} In contrast, FcγRIII is expressed by macrophages only when they are in close contact with decay-accelerating factor–positive fibroblasts or decay-accelerating factor–coated fibrillin-1 microfibrils in the extracellular matrix.²⁶

Cadherins are a class of tissue-restricted transmembrane proteins that play important roles in homophilic intercellular adhesion and are involved in maintaining the integrity of tissue architecture. Cadherin-11, which was cloned from

Figure 2-3 Transmission electron photomicrographs of synovial intimal macrophages (type A cells) and fibroblasts (type B cells). **A**, Low-powered magnification shows the surface fine filopodia, characteristic of macrophages, and a smooth-surfaced nucleus. **B**, The boxed area in **A** is shown at a higher magnification, revealing numerous vesicles, characteristic of macrophages. Absence of rough endoplasmic reticulum also is noted. **C**, The convoluted nucleus along with the prominent rough endoplasmic reticulum (boxed area) is characteristic of a synovial intimal fibroblast (type B cell). **D**, The rough endoplasmic reticulum is shown at greater magnification.

rheumatoid arthritis synovial tissue, is expressed in normal synovial intimal fibroblasts, but not in intimal macrophages. The finding that fibroblasts transfected with cadherin-11 are induced to form a lining-like structure *in vitro* implicates this molecule in the architectural organization of the synovial lining.^{41,42,46} This suggestion is supported by the observation that cadherin-deficient mice have a hypoplastic synovial lining and are resistant to inflammatory arthritis.⁴⁷ When fibroblasts expressing cadherin-11 are embedded in laminin microparticles, they migrate to the surface and form an intimal lining-like structure.⁴⁸ If macrophage lineage cells are included in the culture, they can co-localize with fibroblasts on the surface. These data suggest that the organization of the synovial lining, including the distribution of type A and B cells, is orchestrated by the fibroblast-like synoviocytes.

$\beta 1$ and $\beta 3$ integrins are present on all SLCs, forming receptors for laminin (CD49f and CD49b), collagen types I and IV (CD49b), vitronectin (CD51), CD54 (a member of the immunoglobulin superfamily), and fibronectin (CD49d and CD49e). CD31 (platelet-endothelial cell adhesion molecule), a member of the immunoglobulin superfamily expressed on endothelial cells, platelets, and monocytes, is weakly expressed on SLCs.³²

Turnover of Synovial Lining Cells

Proliferation of SLCs in humans is low, as is seen when normal human synovial explants, exposed to a pulse of ^3H thymidine, cause SLCs to have a labeling index of approximately 0.05% to 0.3%⁴⁹; this bears a striking contrast to labeling indices of approximately 50% for bowel crypt

Figure 2-4 Photomicrographs depicting synovial intimal macrophages by immunohistochemistry. Macrophages are decorated with CD45 (arrow in **A**) and CD68 (**B**)—markers that identify hematopoietic cells (CD45) and macrophages (CD68).

epithelium. Similar evidence of low proliferation has been found in the synovium of rats and rabbits. The proportion of SLCs expressing the proliferation marker Ki67 is between 1 in 2800 and 1 in 30,000, confirming the relatively slow rate of in situ proliferation.⁵⁰ Proliferating cells are generally synovial fibroblasts^{22,51}; this finding is consistent with the concept that type A synovial cells are terminally differentiated macrophages. Mitotic activity of SLCs is low in inflammatory conditions, such as rheumatoid arthritis—a condition associated with SLC hyperplasia. Some groups⁵² have reported only rare mitotic figures in rheumatoid arthritis synovium samples.

Apart from the knowledge that synovial fibroblasts proliferate slowly, little is known about their natural life span, recruitment, or mode of death. Apoptosis likely is involved in maintaining synovial homeostasis, but cultured fibroblast-like synoviocytes tend to be resistant to apoptosis, and very few intimal lining cells display evidence of completed apoptosis by ultrastructural analysis or by labeling for fragmented DNA. The paucity of normal synovium samples for evaluation and the rapid clearance of apoptotic cells could confound the analysis.⁵³

Origin of Synovial Lining Cells

There is little doubt that the type A SLC population is bone marrow derived and represents cells of the mononuclear phagocyte system.⁴ Studies in the Beige (bg) mouse, which harbors a homozygous mutation that confers the presence of giant lysosomes in macrophages, have confirmed the bone marrow origin of these cells.^{54,55} Normal mice, bone marrow depleted through irradiation, were rescued with bone marrow cells obtained from the bg mouse. Electron microscopic analysis of the synovium from recipient animals revealed that type A SLCs contained the giant lysosomes of the donor bg mouse, and that these structures were never identified in type B cells. These findings provide powerful evidence that type A SLCs represent macrophages, that they are recruited from the bone marrow, and that they are a distinct lineage from type B SLCs.

In addition to immunohistochemistry, several lines of evidence have added weight to the concept that type A SLCs are recruited from the bone marrow:

1. The op/op mouse, a spontaneously occurring mutant that fails to produce macrophage colony-stimulating factor because of a missense mutation in the *csf-1* gene,⁵⁶⁻⁵⁸ has low numbers of circulating and resident macrophage colony-stimulating factor-dependent macrophages, including those in the synovium.
2. Type A cells in rat synovium do not populate the joint until after the development of synovial blood vessels.²²
3. Others have reported that type A SLCs were conspicuous around vessels in the synovium in neonatal mice.⁶
4. When synovial explants are placed in culture, the reduction in type A SLCs is explained in part by their migration into the culture medium—an observation that reflects the process of migration of macrophages into the synovial fluid in vivo.^{1,59}
5. Macrophages are found around venules in disease states and constitute 80% of the intimal cells in inflammatory conditions such as rheumatoid arthritis.

Type B intimal cells represent a resident fibroblast population in the synovial lining, but little is known about the cells from which they derive, and about how their recruitment is regulated. The existence of mesenchymal stem cells in the synovium suggests that these might differentiate into the synovial lining fibroblast. To date, a specific transcription factor directing mesenchymal stem cell differentiation into the synovial fibroblast, similar to factors required for commitment by this multipotential population into bone (*cbfa-1*), cartilage (*Sox 9*), and fat (peroxisome proliferator-activated receptor γ [PPAR γ]), has not been identified.

Subintimal Layer

SLCs are not separated from the underlying subintima by a well-formed basement membrane composed of the typical trilaminar structure seen beneath epithelial mucosa.

Nevertheless, most components of basement membrane are present in the extracellular matrix surrounding SLCs. These components include tenascin X, perlecan (a heparan sulfate proteoglycan), collagen type IV, laminin, and fibrillin-1.^{60,61} Of note is the absence of laminin-5 and integrin $\alpha 3 \beta 3 \gamma 2$, which are components of epithelial hemidesmosomes.⁶²

The subintima is composed of loose connective tissue of variable thickness and variable proportions of fibrous/collagenous and adipose tissue, depending on the anatomic site. Under normal healthy conditions, inflammatory cells are virtually absent from the subintima, apart from a sprinkling of macrophages and scattered mast cells.⁶³ Human synovial tissue is a rich source of mesenchymal stem cells, and although it is unknown which compartment contains this cell population, some cells have the ability to self-renew and differentiate into bone, cartilage, and fat *in vitro*—a phenomenon that reflects the ability of the cell to regenerate *in vivo*.⁶⁴⁻⁶⁶

Three categories of subintima are well defined: areolar, fibrous, and fatty/adipose types. Under the light microscope, areolar-type subintima, the most commonly studied, generally is found in larger joints in which there is free movement (Figure 2-5A). It is composed of fronds with a cellular intimal lining and loose connective tissue in the subintima, with little in the way of dense collagen fibers, and a rich vasculature. The fibrous subintima is composed of scant dense fibrous, poorly vascularized connective tissue and has an attenuated layer of SLCs (Figure 2-5B). The adipose type contains abundant mature fat cells and has a single layer of SLCs. This is seen more commonly with aging and in intra-articular fat pads (Figure 2-5C).

The subintima contains collagen types I, III, V, and VI; glycosaminoglycans; proteoglycans; and extracellular matrices including tenascin and laminins. Integrin receptors for collagens, laminin, and vitronectin are absent or at best weakly expressed by subintimal cells. In contrast, receptors for fibronectin (CD49d and CD49e) are detected, and CD44, the HA receptor, is strongly expressed in most subintimal cells. $\beta 2$ integrins are largely limited to perivascular areas, particularly in the subintimal zone, as is CD54.⁶⁷

Subintimal Vasculature

The vascular supply to the synovium is provided by many small vessels and is shared in part by the joint capsule, epiphyseal bone, and other perisynovial structures. Arteriovenous anastomoses communicate freely with the vascular supply to the periosteum and to periarticular bone. As large synovial arteries enter the deep layers of the synovium near the capsule, they branch to form microvascular units in the more superficial subsynovial layers. Precapillary arterioles probably play a major role in controlling circulation to the lining layer. The surface area of the synovial capillary bed is large, and because it runs only a few cell layers deep to the surface, it has a role in trans-synovial exchange of molecules. The intimal lining, however, is devoid of blood vessels.

Numerous physical factors influence synovial blood flow. Heat promotes blood flow through synovial capillaries. Exercise enhances synovial blood flow to normal joints but may reduce the clearance rate of small molecules from

Figure 2-5 Photomicrographs of different morphologic types of synovial tissue. All photomicrographs show an intimal layer of one to two cells in depth. **A**, The areolar synovium is composed of villous fronds. Beneath the intimal lining layer is cellular loose fibrovascular fatty subintima. **B**, The fibrous synovium comprises dense collagenous material in the subintimal layer. **C**, The subintimal layer of the fatty synovial tissue is composed of less cellular mature adipose tissue with little collagen deposition.

the joint space. Experiments have shown a substantial vascular reserve capacity in normal articulations. Immobilization reduces synovial blood flow, and pressure on the synovial membrane can act to tamponade the synovial blood supply.

Vascular endothelial lining cells express CD34 and CD31 (Figure 2-6A). They also express receptors for the

Figure 2-6 Photomicrographs of synovium show lymphovascular and nervous structures by immunohistochemistry. **A** and **B**, Areolar synovium featuring thin-walled vessels are highlighted with antibody to CD31 (**A**), and lymphatic vessels in an inflamed synovium are highlighted with antibody to LYVE-1 (**B**). **C**, Deep in the synovial subintima, close to the joint capsule, are medium-sized neurovascular bundles with nerves highlighted by antibody to S-100. **D**, Within the more superficial synovium, small nerves decorated with S-100 are identified. **E**, The boxed area in **D** is shown at higher magnification; upper arrow is nerve; lower arrow is directed at a small vessel.

major components of basement membrane, including laminin and collagen IV, and the integrin receptors CD49a (laminin and collagen receptors), CD49d (fibronectin receptor), CD41, CD51 (vitronectin receptor), and CD61 (the $\beta 3$ integrin subunit). Endothelial cells express CD44,

the HA receptor, and CD62, P-selectin, which acts as a receptor that supports binding of leukocytes to activated platelets and endothelium. They are only weakly positive in uninflamed synovium, however, for expression of CD54, intercellular adhesion molecule-1, a receptor for $\beta 2$

integrins expressed by many leukocytes. The endothelial cells of capillaries in the superficial zone of the subintima are strongly positive for HLA-DR expression by immunohistochemistry, whereas cells in the larger vessels in the deep aspect of the membrane are negative.^{32,34}

Subintimal Lymphatics

Detailed analysis of the number and distribution of lymphatic vessels has been made possible by the use of the antibody to the lymphatic vessel endothelial HA receptor (LYVE-1) (Figure 2-6B).⁶⁸ This antibody is highly specific for lymphatic endothelial cells in lymphatic vessels and lymph node sinuses and does not react with endothelial cells of capillaries and other blood vessels that express CD34 and factor VIII-related antigen. Expression of LYVE-1 in lymphatic endothelial cells has been used as a marker to show that lymphatic vessels are less common in the fibrous synovium compared with areolar and adipose variants of human subsynovial tissue. Detection of this molecule reveals that lymphatics are present in the superficial, intermediate, and deeper layers of synovial membrane in synovium from normal individuals or patients with osteoarthritis and rheumatoid arthritis joints, although the number in the superficial subintimal layer is low in normal synovium. Little difference in the distribution and number is noted between normal and osteoarthritis synovium, which is characterized by lack of villous hypertrophy. Lymphatic channels are plentiful, however, in the subintimal layer in the presence of villous edema hypertrophy and chronic inflammation.

Subintimal Nerve Supply

The synovium has a rich network of sympathetic and sensory nerves. The former, which are myelinated and detected with the antibody against S-100 protein, terminate close to blood vessels, where they regulate vascular tone (Figure 2-6C through E). Sensory nerves respond to proprioception and pain via large myelinated nerve fibers and via small (<5 μm) unmyelinated or myelinated fibers with unmyelinated free nerve ends (nociceptors). The latter are immunoreactive in the synovium for neuropeptides, including substance P, calcitonin gene-related peptide, and vasoactive intestinal peptides.^{69,70}

FUNCTION

Known synthetic and protective functions of individual synovial cell populations are multiple and complex. The composite synovial structure, which includes cell populations and their products, vasculature, nerves, and the intercellular matrix, possesses several specialized functions that are essential for normal joint movement, synovial fluid formation, chondrocyte nutrition, and cartilage protection at multiple anatomic locations. These functions must be preserved over a lifetime to maintain maximal mobility and independence. Absence of essential constituents of synovial fluid, or inadequate cartilage protection, results in early articular malfunction, which may progress to local or generalized joint failure.

Joint Movement

Four characteristics of the synovium are essential for joint movement: deformability, porosity, nonadherence, and cartilage lubrication. In health, the synovium is a highly deformable structure that facilitates movement between other adjacent, nondeformable structures within the joint. This unique facility of the synovium to enable movement between, rather than within, tissues has been emphasized⁷¹ and can be attributed to the presence of a free surface that allows synovial tissue to remain separated from adjacent tissues. The ensuing space is maintained by the presence of synovial fluid.

Deformability

The deformability of normal synovium is considerable because it must accommodate the extreme positional range available to the joint and its adjacent tendons, ligaments, and capsule. When a finger is flexed, the palmar synovium of each interphalangeal joint contracts, while the dorsal synovium expands, and as the finger extends, the reverse occurs. This normal contraction and expansion of synovium seems to involve a folding and unfolding component and an elastic stretching and relaxation of the tissue. It is essential that during repeated rapid movement, synovial lining does not become pinched between cartilage surfaces and can successfully retain its integrity and the integrity of synovial blood vessels and lymphatics. Deformability also limits the extent of synovial ischemia-reperfusion injury during joint motion by maintaining a relatively low intra-articular pressure.

Porosity

The synovial microvasculature and the intimal lining must be porous to permit robust diffusion of nutrients to cartilage. The structure of the intimal lining is ideal for this requirement because of the relatively disorganized basement membrane and lack of tight junctions. Plasma components freely diffuse into the intra-articular space, and most plasma components, including proteins, are present in synovial fluid at about one-third to one-half the plasma concentration.

Nonadherence

The third important characteristic of the synovium that facilitates joint movement is its nonadherence to opposing surfaces. Intimal cells on the synovial surface adhere to underlying cells and matrix but do not adhere to opposing synovial and cartilage surfaces. The mechanism that preserves this phenomenon of nonadherence is unknown and might involve the arrangement of cell surface and tissue matrix molecules, such as collagen, fibronectin, and HA. Alternatively, nonadherence may result in part from regular movements of the normal synovial lining.

Lubrication

The fourth characteristic of synovium that is essential for joint motion is an efficient lubrication mechanism to

facilitate movement of cartilage on cartilage. The mechanisms of joint lubrication are complex and are an integral component of synovial physiology. In an articulating joint, cartilage is subjected to numerous compressive and frictional forces every day. Friction and wear can never be eliminated from a functioning joint. Adult chondrocytes do not normally divide *in vivo*, and damaged cartilage has limited capacity for self-repair. For a joint to maintain its function throughout a lifetime of use, protective biologic mechanisms, such as lubrication, help minimize wear and damage that result from normal daily activities.

Boundary lubrication refers to the protective effect of particular lubricating molecules adsorbing to a surface and repelling its opposing interface.⁷² Bearing surfaces must generate a mutual repulsion to be lubricated in the boundary mode. Boundary lubricants exert their effects by changing the physicochemical characteristics of a surface and reduce articular friction and wear by providing a smooth and slippery coating. Friction is reduced by an interposed film of protective fluid that allows one surface to ride freely over another. The cartilage matrix is integral to this phenomenon because it is fluid filled and compressible. Loaded cartilage extrudes lubricant fluid from its surface, and expressed fluid contributes to the separation of the two articulating surfaces. Scanning electron microscopy has shown a continuous film of fluid, only 100 nm thick, which separates one surface from the other, preventing direct abrasive contact.⁷³ This ultrathin coating of lubricant resists distraction of the two articulating surfaces, enhancing joint stability. Another essential advantage of an intra-articular lubrication system is the effective prevention of pinching of adjacent, well-vascularized synovial membrane.

Hyaluronic Acid

HA, a high-molecular-weight polysaccharide, is a major component of synovial fluid and cartilage.⁷⁴ It is produced in large amounts by mechanosensitive, fibroblast-like synoviocytes.^{75,76} HA, of which three mammalian forms are designated HAS1, HAS2, and HAS3,⁷⁷ is synthesized by HA synthase at the plasma membrane and is extruded directly into the extracellular compartment. HA synthase activity and HA secretion are stimulated by proinflammatory cytokines, including interleukin-1 β and transforming growth factor- β .^{75,78,79} HA also is synthesized by many other skeletal cells and is an important component of extracellular matrices. It is simultaneously a solid phase matrix element of cartilage and other tissues, and a fluid phase element in the synovial space under normal and abnormal conditions.

HA has many biologic functions, which include effects on cell growth, migration, and adhesion. The regulatory role of HA is mediated through HA-binding proteins and receptors, including CD44, which are present on the cell surfaces of chondrocytes, lymphocytes, and other mononuclear cell populations. HA plays a crucial role in morphogenesis and in wound healing. Additionally, HA is a vital structural component of the synovial lining, and it has an essential role in the induction of joint cavitation during embryogenesis. HA, produced by synovium, was originally thought to be primarily a joint lubricant, and it is generally accepted that it plays a major physiologic role in

maintaining synovial fluid viscosity. It is important in normal joint function, not least through its capacity to provide effective shock absorption. It has been suggested that HA is a particularly important viscohydrodynamic lubricant at low-load interfaces, such as synovium-on-synovium and synovium-on-cartilage.⁸⁰ Synovial fluid HA, acting in combination with albumin, has a role in the attenuation of fluid loss from the joint cavity, particularly during periods of increased pressure, which can occur during sustained joint flexion.⁸¹⁻⁸³

Lubricin. Compelling evidence suggests that lubricin, first described in the 1970s,⁸⁴ is the factor primarily responsible for boundary lubrication of diarthrodial joints.⁸⁵ Lubricin, a large secreted, mucin-like proteoglycan with an apparent molecular weight of 280 kD, is a product of the gene proteoglycan 4 (PRG4). It is a major component of synovial fluid and is present at the cartilage surface. The gene is highly expressed by human synovial fibroblasts and by superficial zone chondrocytes.⁸⁶ Lubricin is closely related to superficial zone protein, megakaryocyte-stimulating factor, and hemangiopoietin, which are encoded by the same gene but can differ in terms of posttranslational modification. Superficial zone protein is expressed by SLCs and by superficial zone chondrocytes at the cartilage surface, but not by intermediate or deep zone chondrocytes.⁸⁷ It has been suggested that lubricin may bind to the much longer hyaluronate polymers, distributing shear stress and stabilizing essential lubricant molecules.⁸⁸

In an experimental model, lubricin seemed to have multiple functions in articulating joints and tendons, including protection of cartilage surfaces from protein deposition and cell adhesion and inhibition of synovial cell overgrowth.⁸⁹ *Prp4*^{-/-} mice, consistently normal at birth, showed progressive loss of superficial zone chondrocytes and increasing synovial cell hyperplasia (Figure 2-7). The essential role of lubricin in maintaining joint integrity was shown by the identification of disease-causing mutations in patients with the autosomal recessive disorder camptodactyly-arthropathy-coxa vara-pericarditis (CACP) syndrome.⁹⁰ CACP is a large joint arthropathy associated with the absence of lubricin from synovial fluid and ineffective boundary lubrication provided by the synovial fluid (Figure 2-8).^{88,91} In other studies of lubricin biology and joint integrity, experimental injury resulted in reduced synovial fluid lubricin concentrations, decreased boundary lubricating ability, and increased cartilage matrix degradation, each of which could be attributed to trauma-induced inflammatory processes.⁸⁶

Others have argued against the primacy of lubricin in joint lubrication by proposing that surface-active phospholipid, also secreted by intimal fibroblasts, is the essential boundary lubricant that reduces cartilage friction to remarkably low levels.⁹² It was hypothesized that lubricin acts as the carrier of surface-active phospholipid to articular cartilage but is not the lubricant *per se*, a function that is similar to that of the well-characterized alveolar surfactant binding proteins in the lung.

Formation of Synovial Fluid

In health, a constant volume of synovial fluid is important during joint movement as a cushion for synovial tissue and

Figure 2-7 Clinical appearance and radiographic changes in *Prg4*^{-/-} mice. **A** and **B**, Photographs of the hind paws of 6-month-old *Prg4*^{-/-} (**A**) and wild-type (**B**) mice. Note the curved digits in the mutant mouse and swelling at the ankle joint. **C** and **D**, Radiographs of the ankle joint of 9-month-old wild-type (**C**) and *Prg4*^{-/-} mice (**D**). Structures corresponding to the tibia (t) and talus (ta) are indicated. Note the calcification of structures adjacent to the ankle (arrows in **D**). **E**, Lateral knee x-ray of a 4-month-old wild-type mouse. Structures corresponding to the patella (p), femoral condyle (f), tibial plateau (t), and fibula (fib) are indicated. **F**, Lateral knee x-ray of a 4-month-old *Prg4*^{-/-} mouse. Note the increased joint space between the patella and femur (arrow) and osteopenia of the patella, femoral condyles, and tibial plateau. **G**, Shoulder x-ray of a 4-month-old wild-type mouse. Structures corresponding to the humeral head (h), glenoid fossa of the scapula (s), and lateral portion of the clavicle (c) are indicated. **H**, Shoulder x-ray of a 4-month-old *Prg4*^{-/-} mouse. Note the increased joint space between the humerus and scapula (arrow) and osteopenia of the humeral head. (From Rhee DK, Marcelino J, Baker M, et al: The secreted glycoprotein lubricin protects cartilage surfaces and inhibits synovial cell overgrowth, *J Clin Invest* 115:622–631, 2005.)

Figure 2-9 Schematic representation of the formation of synovial fluid. Many of the soluble components and proteins in synovial fluid exit the synovial subintimal microcirculation through pores or fenestrations in the vascular endothelium, then diffuse through the interstitium before entering the joint space. Synovial permeability to most small molecules is determined by a process of free diffusion through the double barrier of endothelium and interstitium, limited mainly by the intercellular space between synovial lining cells. Fat-soluble molecules can diffuse through, and between, cell membranes; their passage across the synovial surface is less restricted. Additional components, including hyaluronan and lubricin, are produced by synovial lining cells.

as a reservoir of lubricant for cartilage. Many of the soluble components and proteins in synovial fluid exit the synovial microcirculation through pores or fenestrations in the vascular endothelium, then diffuse through the interstitium before entering the joint space. Synovial fluid is in part a filtrate of plasma to which additional components, including HA and lubricin, are added and removed by the SLCs (Figure 2-9). As noted earlier, concentrations of electrolytes and small molecules in synovial fluid are similar to those in plasma. Synovial permeability to most small molecules is determined by a process of free diffusion through the double barrier of endothelium and interstitium, limited mainly by the intercellular space between SLCs. For most small molecules, synovial permeability is inversely related to the dimensions of the molecule.

Experimental evidence suggests that the exchange of small solutes is determined predominantly by the synovial interstitium, and that permeability to proteins is mainly determined by the microvascular endothelium. The synovium should not be regarded as simply an inert membrane, but as a complex regulatory tissue system. The small physiologic molecules that traverse the endothelium of synovial blood vessels and diffuse through intercellular spaces of the synovial lining before entering the synovial fluid include water, glucose, and many other essential nutrients and waste tissue metabolites. Evidence suggests that passage of some solutes across the synovium is facilitated by specific transport systems that provide, possibly, a “pump” mechanism capable of moving water out of the joint space.

Plasma proteins are able to cross the endothelium, traversing the synovial interstitium and entering the synovial fluid. The efficiency of this process is determined by the molecular size of the protein and the diameter of the endothelial pores. Smaller proteins, such as albumin, enter easily, whereas larger molecules, such as fibrinogen, gain access with greater difficulty. In contrast, the clearance or removal of proteins and other synovial fluid constituents is unrestricted and considerably more efficient through lymphatic

drainage. The synovial fluid concentration of any protein reflects the dynamic balance between ingress and egress at a given time. Because egress is more efficient than ingress, joint space pressure is normally subatmospheric. Negative intra-articular pressure is thought to be important in maintaining joint stability. The synovial fluid-to-serum ratio of plasma proteins is inversely related to the molecular size of the protein. When the joint becomes inflamed, greater endothelial permeability permits more profuse ingress of all proteins, and the most obvious changes are noted in the concentrations of larger molecules. Increased synovial fluid volume also reduces the stability of the joint.

In contrast to hydrophilic molecules, fat-soluble molecules can diffuse through and between cell membranes, and their passage across the synovial surface is less restricted. The entire surface area of the synovium is available to lipophilic molecules that diffuse into and out of the joint space. Physiologically, the most important fat-soluble molecules are the respiratory gases, oxygen and carbon dioxide. When the joint is inflamed, synovial fluid may exhibit low partial pressure of oxygen, high partial pressure of carbon dioxide, decreased pH, and increased lactate production.⁹³ The resultant hypoxia and acidosis can have serious implications for the synovial microcirculation and chondrocyte metabolism.

Nutrition of Chondrocytes

Another important function of synovium is to enhance the nutrition of chondrocytes, which are resident in articular cartilage (see Chapter 3). Because articular cartilage is avascular, delivery of nutrients to chondrocytes and removal of metabolic breakdown products from the cartilage are believed to occur through synovial fluid and synovial tissue arterioles and venules, as well as through subchondral bone. Morphologic, physiologic, and pathologic studies have confirmed that solutes pass easily from the synovial fluid into cartilage, and that cartilage does not survive without synovial fluid contact *in vivo*. Within the cartilage matrix, three potential mechanisms for nutrient transfer have been proposed: diffusion, active transport by chondrocytes, and pumping by intermittent compression of cartilage matrix. A large proportion of hyaline cartilage lies within 50 μm of a synovial surface and its rich supply of blood vessels. Chondrocytes are oxygen sensitive and are well adapted to living in hypoxic conditions. Low oxygen tension promotes expression of the chondrocyte phenotype and cartilage-specific matrix formation. Reactive oxygen species also may play a crucial role in the regulation of some normal chondrocytic activities, such as cell activation, proliferation, and matrix remodeling.

SUMMARY

The normal human synovial membrane is a highly specialized, multifunctional organ that is vital for mobility, independence, and survival. The intimal layer is composed of two distinct cell phenotypes with characteristics of macrophage and fibroblast lineages. Synovial macrophages express CD45, CD163 and CD97, CD68, neuron-specific esterase, and cathepsins B, L, and D. Cells expressing CD14 are rarely seen in the healthy intimal layer. Fc γ RIII

(CD16), expressed by Kupffer cells of the liver and type II alveolar macrophages of the lung, is expressed on a subpopulation of synovial macrophages. Synovial macrophages also express the MHC class II molecule and play a central role in phagocytosis and in antigen-mediated immune responses.

Synovial intimal fibroblasts possess prominent synthetic capacity and produce the essential joint lubricants HA and lubricin. They also synthesize normal matrix components, including fibronectin, laminin, collagens, proteoglycans, lubricin, and other identified and unidentified proteins. They have the capacity to produce large quantities of metalloproteinases, metalloproteinase inhibitors, prostaglandins, and cytokines. Expression of selected adhesion molecules on synovial fibroblasts probably facilitates the trafficking of some cell populations, such as polymorphs, into synovial fluid, and the retention of others, such as mononuclear leukocytes, within synovial tissue.

The subintimal layer is composed of a loose connective tissue matrix and contains branching blood and lymphatic vessels; a nerve supply; and a variety of resident cell populations, including infiltrating macrophages and fibroblasts. The nerve supply is important in regulating synovial blood flow. Lymphatic vessels allow egress of metabolic breakdown products from the synovium and synovial fluid. The morphology of the subintimal layer varies according to the anatomic location and the local functional requirements.

Coordinated functions of the composite synovial membrane are essential for normal joint movement, formation of synovial fluid, nutrition of chondrocytes, and protection of cartilage. These functions must be preserved over a lifetime at multiple anatomic locations. Absence of essential constituents of synovial fluid, such as lubricin, or inadequate cartilage protection results in early articular malfunction, which may progress to variable degrees of joint failure. The characteristics of lubricin deficiency have been elegantly described in animal models and in humans. Additional studies may define novel clinical categories of degenerative polyarthritis that are associated with other specific disorders of synovial membrane function.

Cartilage and Chondrocytes

MARY B. GOLDRING

KEY POINTS

Articular cartilage matrix is heterogeneous and contains numerous extracellular matrix (ECM) proteins, of which the large aggregating proteoglycan aggrecan and collagen types II, IX, and XI are the major constituents.

The collagen network of cartilage confers tensile strength, and aggrecan provides resistance to compression.

Adult articular chondrocytes are nonmitotic cells that survive at low oxygen tension in the absence of a vascular supply.

In response to trauma or inflammation, the metabolic activity of the chondrocyte is increased in response to catabolic and anabolic factors that regulate remodeling of the ECM.

Under physiologic conditions, the chondrocyte maintains low-turnover repair of proteoglycans, but the repair capacity, responses to anabolic factors, cell survival, and quality of the matrix decline with age.

Hyaline cartilage, including the articular cartilage of diarthrodial joints, consists of a single cellular component, the chondrocyte, which is embedded in a unique and complex matrix. Adult articular chondrocytes are considered to be fully differentiated cells that maintain matrix constituents in a low-turnover state of equilibrium. Chondrocytes serve diverse functions during development and postnatal life. In the embryo, the chondrocyte arises from mesenchymal progenitors from diverse sources, including the cranial neural crest of the neural ectoderm, cephalic mesoderm, sclerotome of the paraxial mesoderm, and somatopleure of the lateral plate mesoderm, depending upon the ultimate location of the cartilage. The chondrocyte synthesizes the templates, or cartilage anlagen, through a process termed *chondrogenesis*.

After mesenchymal condensation and chondroprogenitor cell differentiation, the chondrocytes undergo proliferation, terminal differentiation to chondrocyte hypertrophy, and apoptosis through a process termed *endochondral ossification*, whereby the hypertrophic cartilage is replaced by bone. A similar sequence of events occurs in the postnatal growth plate and leads to rapid growth of the skeleton. Processes that control the different stages of skeletal development are described in Chapter 1.

In adults, the anatomic distribution of cartilage is restricted primarily to the joints, trachea, and nasal septum, where the major function is structural support. In joints, cartilage has the additional function of providing low-friction articulation. Adult articular cartilage comprises a specialized matrix of collagens, proteoglycans, and other cartilage-specific and nonspecific proteins. Adult articular

chondrocytes, remnants of the resting, or reserve, chondrocytes that laid down the original cartilage matrix during chondrogenesis, are inactive metabolically, owing partially to the absence of a vascular supply and innervation in the tissue.¹ The clinical importance of the adult chondrocyte resides in its capacity to respond to mechanical stimuli, growth factors, and cytokines that may influence normal homeostasis in a positive or negative manner. In rheumatoid arthritis (RA), cartilage destruction occurs primarily in areas contiguous with the proliferating synovial pannus, although evidence indicates that the chondrocyte can respond to the inflammatory milieu and participate in degrading its own matrix.² In osteoarthritis (OA), the chondrocyte plays a key role by reacting to structural changes in the surrounding cartilage matrix through the production of catabolic cytokines and anabolic factors, which act in an autocrine-paracrine manner.^{3,4} Nevertheless, the chondrocyte has limited capacity, which declines with age, to regenerate the normal cartilage architecture with zonal variations in the matrix network that was formed originally. This chapter focuses on the structure and function of normal articular cartilage and the role of the chondrocyte in maintaining cartilage homeostasis and responding to adverse environmental insults that may modify cartilage integrity.

CARTILAGE STRUCTURE

Normal articular cartilage is a specialized tissue characterized macroscopically by its milky, shelled-almond (hyaline) appearance. It is an avascular tissue nourished by diffusion from the vasculature of the subchondral bone and from the synovial fluid. Articular cartilage is more than 70% water, and it is hypocellular compared with other tissues; chondrocytes constitute only 1% to 2% of its total volume.^{5,6} Most of the dry weight of cartilage consists of two components: type II collagen and the large aggregating proteoglycan, aggrecan. Several “minor” collagens and small proteoglycans also seem to play a role in cartilage-matrix organization, however.^{7,8}

Organic constituents represent only about 20% of the wet weight of cartilage. Collagen, primarily type II, accounts for approximately 15% to 25% of the wet weight and about half of the dry weight except in the superficial zone, where it represents most of the dry weight. Proteoglycans, primarily aggrecan, account for 10% of the wet weight and about 25% of the dry weight. The highly cross-linked type II collagen-containing fibrils form a systematically oriented network that traps the highly negatively charged proteoglycan aggregates.⁹ Histochemical analysis of cartilage shows that proteoglycans can be stained reliably with safranin O,

toluidine blue, or Alcian blue, although at low substrate concentrations, these methods are not stoichiometric.¹⁰ Collagen also can be stained efficiently, but differentiation of collagen types requires immunostaining with specific antibodies.

Despite its thinness (≤ 7 mm) and apparent homogeneity, mature articular cartilage is a heterogeneous tissue with four distinct regions: (1) the superficial tangential (or gliding) zone, (2) the middle (or transitional) zone, (3) the deep (or radial) zone, and (4) the calcified cartilage zone, which is located immediately below the tidemark and above the subchondral bone (Figure 3-1).^{6,9,11,12} In the superficial zone, the chondrocytes are flattened, and the matrix comprises thin collagen fibrils in tangential array, associated with a high concentration of the small proteoglycan decorin and a low concentration of aggrecan. The middle zone, composing 40% to 60% of cartilage weight, consists of rounded chondrocytes surrounded by radial bundles of thick collagen fibrils. In the deep zone, chondrocytes frequently are grouped in columns or clusters (Figure 3-2). In this region, collagen bundles are the thickest and are arranged in a radial fashion.

Cell density progressively decreases from the surface to the deep zone, where it is one-half to one-third the density in the superficial zone¹³; chondrocytes in the deep and middle zones have a cell volume that is twice that of superficial chondrocytes.¹⁴ Water is 75% to 80% of the wet weight in the superficial zone and progressively decreases to 65% to 70% with increasing depth. Greater amounts of collagen relative to proteoglycans are present in the superficial zone, compared with the middle and deep zones, and type I collagen may be synthesized, in addition to type II collagen.^{15,16} With increasing depth, the proportion of proteoglycan increases to 50% of the dry weight in the deep zone.^{14,17-19} The calcified zone is formed as a result of endochondral ossification and persists after growth plate closure as the histologically defined tidemark.²⁰ The calcified zone serves as an important mechanical buffer between uncalcified articular cartilage and subchondral bone.

The physical properties of articular cartilage are determined by the unique fibrillar collagen network, which provides tensile strength, interspersed with proteoglycan aggregates that bestow compressive resilience.²¹⁻²³

Figure 3-1 The structure of human adult articular cartilage, showing zones of cellular distribution and the pericellular, territorial, and interterritorial regions of matrix organization. Insets show the relative diameters and orientations of collagen fibrils in the different zones. The positions of the tidemark and subchondral bone and other special features of matrix composition also are noted. (From Poole AR, Kojima T, Yasuda T, et al: *Composition and structure of articular cartilage: a template for tissue repair*, Clin Orthop Relat Res [391S]:S26–S33, 2001. Copyright Lippincott Williams & Wilkins.)

Figure 3-2 Light micrograph of vertically sectioned adult human cartilage (femoral condyle), illustrating its subdivision into superficial (S), transitional (T), upper radial (U), lower radial (L), and calcified cartilage (M) zones; the last mentioned abuts on the subchondral bone plate (B). Saw-cut, 100 μ m thick surface stained with basic fuchsin, McNeil's tetra-chrome, and toluidine blue O. (From Hunziker EB: *Articular cartilage structure in humans and experimental animals*. In Kuettner KE, Schleyerbach R, Peyron JG, et al, editors: *Articular cartilage and osteoarthritis*, New York, 1992, Raven, pp 183–199.)

Proteoglycans are associated with large quantities of water bound to the hydrophilic glycosaminoglycan chains. This cartilaginous extracellular matrix (ECM), with its tightly bound water, provides a high degree of resistance to deformation by compressive forces. The capacity to resist compressive forces is associated with the ability to extrude water

as the cartilage compresses. When compression is released, the proteoglycans (now depleted of balancing counter ions that were removed with the water) contain sufficient fixed charge to reabsorb osmotically the water and small solutes into the matrix, which then rebounds to its original dimensions.^{24,25}

STRUCTURE-FUNCTION RELATIONSHIPS OF CARTILAGE MATRIX COMPONENTS

ECM components synthesized by chondrocytes include highly cross-linked fibrils of triple-helical type II collagen molecules that interact with other collagens, aggrecan, small proteoglycans, and other cartilage-specific and non-specific matrix proteins (Table 3-1).^{5,7,8,11} The importance of these structural proteins may be observed in heritable disorders, such as chondrodysplasias, or in transgenic animals in which mutations or deficiencies in cartilage genes result in cartilage abnormalities.²⁶⁻³⁰ Deficiencies or disruptions in genes that encode the cartilage-specific collagens result, in some cases, in premature OA.²⁸ Knowledge of the composition of the cartilage matrix has permitted the development of methods for identifying molecular markers in serum and synovial fluid that can be used to monitor changes in cartilage metabolism and to assess cartilage damage in OA or RA.³¹⁻³⁴ Changes in the structural composition of cartilage can markedly affect its biomechanical properties (see Chapter 6).

Cartilage Collagens

The major component of the collagen network in adult articular cartilage is the triple-helical type II collagen molecule, which is composed of three identical α chains ($\alpha 1(\text{II})$)₃. These molecules are assembled in fibrils in a quarter-stagger array that can be observed by electron microscopy.^{7,35,36} These fibrils are thinner than type I collagen-containing fibrils in skin because of the higher numbers of hydroxylysine residues that can form cross-links and the presence of other collagen and noncollagen

Table 3-1 Extracellular Matrix Components of Cartilage

Molecule	Structure and Size	Function and Location
Collagens		
Type II	$[\alpha 1(\text{II})]_3$; fibril-forming	Tensile strength; major component of collagen fibrils
Type IX	$[\alpha 1(\text{IX})\alpha 2(\text{IX})\alpha 3(\text{IX})]$; single CS or DS chain; $\alpha 1(\text{II})$ gene encodes $\alpha 3(\text{IX})$; FACIT	Tensile properties, interfibrillar connections; cross-links to surface of collagen fibril, NC4 domain projects into matrix
Type XI	$[\alpha 1(\text{XI})\alpha 2(\text{XI})\alpha 3(\text{XI})]$; fibril-forming	Nucleation/control of fibril formation; within collagen fibril
Type VI	$[\alpha 1(\text{VI})\alpha 2(\text{VI})\alpha 3(\text{VI})]$; microfibrils	Forms microfibrillar network, binds hyaluronan, biglycan, decorin; pericellular
Type X	$[\alpha 1(\text{X})]_3$; hexagonal network	Support for endochondral ossification; hypertrophic zone and calcified cartilage
Type XII	$[\alpha 1(\text{XII})]_3$; FACIT large cruciform NC3 domain	Associated with type I collagen fibrils in perichondrium and articular surface
Type XIV	$[\alpha 1(\text{XIV})]_3$; FACIT	Associated with type I collagen; superficial zone
Type XVI	$[\alpha 1(\text{XVI})]_3$; FACIT	Integrates with collagen II/XI fibrils
Type XXVII	<i>Col27a1</i> gene: 156 kb, 61 exons	Fibril-forming; developing cartilage

Continued

Table 3-1 Extracellular Matrix Components of Cartilage—cont'd

Molecule	Structure and Size	Function and Location
Proteoglycans		
Aggrecan	255 kD core protein; CS/KS side chains; C-terminal EGF and lectin-like domains	Compressive stiffness through hydration of fixed charge density; binding through G1 domain to HA stabilized by link protein
Versican	265-370 kD core protein; CS/DS side chains; C-terminal EGF, C-type lectin, and CRP-like domains	Low levels in articular cartilage throughout life; calcium-binding and selectin-like properties
Perlecan	400-467 kD core protein; HS/CS side chains; no HA binding	Cell-matrix adhesion; pericellular
Biglycan	38 kD; LRR core protein with two DS chains (76 kD)	Binds collagen VI and TGF- β ; pericellular
Decorin	36.5 kD; LRR core protein with one CS or DS side chain (100 kD)	Controls size/shape of collagen fibrils, binds collagen II and TGF- β ; interterritorial
Asporin	40 kD; LRR core protein; N-terminal extension of 15 aspartate residues	Binds collagen, modulates TGF- β function
Fibromodulin	42 kD; containing KS chains in central LRR region and N-terminal tyrosine sulfate domains	Same as decorin
Lumican PRELP	38 kD; structure similar to fibromodulin 44 kD; LRR core protein; proline-rich and arginine-rich N-terminal binding domain for heparin and HS	Same as decorin Mediates cell binding through HS in syndecan
Chondroadherin	45 kD; LRR core protein without N-terminal extension	Binding to cells via $\alpha 2\beta 1$ integrin
Other Molecules		
Hyaluronic acid (HA; hyaluronan)	1000-3000 kD	Retention of aggrecan within matrix
Link protein	38.6 kD	Stabilizes attachment of aggrecan G1 domain to HA
Cartilage oligomeric matrix protein (COMP)	550 kD; five 110-kD subunits; thrombospondin-like	Interterritorial in articular cartilage; stabilizes collagen network or promotes collagen fibril assembly; calcium binding
Cartilage matrix protein (CMP, or matrilin-1); matrilin-3	Three 50-kD subunits with vWF and EGF domains	Tightly bound to aggrecan in immature cartilage
Cartilage intermediate layer protein (CILP)	92 kD; homology with nucleotide pyrophosphohydrolase without active site	Restricted to middle/deep zones of cartilage; increase in early and late osteoarthritis
Glycoprotein (gp)-39, YKL-40, or chitinase 3-like protein 1 (CH3L1)	39 kD; chitinase homology	Marker of cartilage turnover; chondrocyte proliferation; superficial zone of cartilage
Fibronectin	Dimer of 220 kD subunits	Cell attachment and binding to collagen and proteoglycans; increased in osteoarthritis cartilage
Tenascin-C	Six 200-kD subunits forming hexabrachion structure	Binds syndecan-3 during chondrogenesis; angiogenesis
Superficial zone protein (SZP), lubricin, or proteoglycan (PRG) 4	225 kD, 200 nm length	Joint lubrication; superficial zone only
Membrane Proteins		
CD44	Integral membrane protein with extracellular HS/CS side chains	Cell-matrix interactions; binds HA
Syndecan-1, -3, -4	N-terminal HS attachment site; cytoplasmic tyrosine residues	Syndecan-3 is receptor for tenascin-C during cartilage development; cell-matrix interactions
Anchorin CII (or annexin V)	34 kD; homology to calcium-binding proteins calpactin and lipocortin	Cell surface attachment to type II collagen; calcium binding
Integrins ($\alpha 1$, $\alpha 2$, $\alpha 3$, $\alpha 5$, $\alpha 6$, $\alpha 10$; $\beta 1$, $\beta 3$, $\beta 5$)	Two noncovalently linked transmembrane glycoproteins (α and β subunits)	Cell-matrix binding: $\alpha 1\beta 1$ /collagen I or VI, $\alpha 2\beta 1$ or $\alpha 3\beta 1$ /collagen II, $\alpha 5\beta 1$ /fibronectin; intracellular signaling
Discoidin domain receptor 2	Receptor tyrosine kinase	Binds native type II collagen fibrils; Ras/ERK signaling

CRP, complement regulatory protein; CS, chondroitin sulfate; DS, dermatan sulfate; EGF, epidermal growth factor; FACIT, fibril-associated collagens with interrupted triple helices; HA, hyaluronic acid; HS, heparan sulfate; KS, keratan sulfate; LRR, leucine-rich repeat; NC, noncollagen; PRELP, proline-rich and arginine-rich end leucine-rich repeat protein; TGF, transforming growth factor; vWF, von Willebrand factor.

components in the fibril. Type IIB collagen in articular cartilage is a product of alternative splicing and lacks a 69 amino acid, cysteine-rich domain of the amino-terminal propeptide, which is encoded by exon 2 in the human type II collagen gene (*COL2A1*).³⁷ This domain is found in type IIA procollagen, which is expressed by chondroprogenitor

cells during development, and in the amino propeptides of other interstitial collagen types, and may play a feedback-inhibitory role in collagen biosynthesis. The reappearance of type IIA collagen in the midzone pericellular matrix and type X collagen, the hypertrophic chondrocyte marker, in the deep zone of OA cartilage suggests reversion to a

developmental phenotype in an attempt to repair the damaged matrix.^{38,39}

Although collagens VI, IX, XI, XII, and XIV are quantitatively minor components, they may have important structural and functional properties. Collagens IX and XI are specific to cartilage, whereas collagens VI, XII, and XIV are widely distributed in other connective tissues.⁷ Collagen VI, which is present in cartilage as microfibrils in very small quantities in the pericellular matrix, may play a role in cell attachment and interacts with other matrix proteins, such as hyaluronan, decorin, and biglycan. Small amounts of collagen III are found in cartilage, and collagen VI may increase in OA cartilage.³⁹

Type IX collagen is a proteoglycan and a collagen because it contains a chondroitin sulfate chain attachment site in one of the noncollagen domains. The helical domains of the type IX collagen molecule form covalent cross-links with type II collagen telopeptides and are attached to the fibrillar surface, as observed by the electron microscope. Type IX collagen may function as a structural intermediate between type II collagen fibrils and the proteoglycan aggregates, serving to enhance the mechanical stability of the fibril network and resist the swelling pressure of the trapped proteoglycans. Destruction of type IX collagen accelerates cartilage degradation and loss of function.^{7,35,36}

The $\alpha 3$ chain of type XI collagen has the same primary sequence as the $\alpha 1(\text{II})$ chain, and the heterotrimeric type XI collagen molecule is buried in the same fibril as type II collagen. Type XI collagen may have a role in regulating fibril diameter. The more recently discovered nonfibrillar fibril-associated collagens with interrupted triple helices (FACIT), XII and XIV, which are structurally related to type IX collagen, do not form fibrils by themselves but co-aggregate with fibril-forming collagens and modulate the packing of collagen fibers through domains projecting from their surfaces.^{7,35,36}

Cartilage Proteoglycans

The major proteoglycan in articular cartilage is the large aggregating proteoglycan, or aggrecan, which consists of a core protein of 225 to 250 kD with covalently attached side chains of glycosaminoglycans, including approximately 100 chondroitin sulfate chains, 30 keratan sulfate chains, and shorter N-linked and O-linked oligosaccharides.^{5,8,40,41} Link protein, a small glycoprotein, stabilizes the noncovalent linkage between aggrecan and hyaluronic acid (also called *hyaluronan*) to form the proteoglycan aggregate that may contain 100 aggrecan monomers. The G1 and G2 N-terminal globular domains of aggrecan and its C-terminal G3 domain have distinct structural properties that function as integral parts of the aggrecan core protein and contribute cleavage products that accumulate with age or in OA. The G2 domain is separated from G1 by a linear interglobular domain and has two proteoglycan tandem repeats. The G3 domain contains sequence homologies to epidermal growth factor, lectin, and complement regulatory protein, and participates in growth regulation, cell recognition, intracellular trafficking, and recognition, assembly, and stabilization of the ECM. About half of the aggrecan molecules in adult cartilage lack the G3 domain, probably as a result of proteolytic cleavage during matrix turnover. Small quantities

of other large proteoglycans are found in cartilage, including versican, which forms aggregates with hyaluronic acid, and perlecan, which is nonaggregating; however, these proteoglycans function primarily during skeletal development, where versican is expressed in prechondrogenic condensations, and perlecan is expressed in the cartilage anlagen after expression of type II collagen and aggrecan.⁴¹

The nonaggregating small proteoglycans are not specific to cartilage, but in cartilage they serve specific roles in matrix structure and function, primarily by modulating collagen-fibril formation.⁴²⁻⁴⁴ Of the more than 10 leucine-rich repeat (LRR) proteoglycans discovered so far, only osteoadherin is not present in cartilage. The 24 amino acid central LRR domain is conserved, but the N-terminal and C-terminal domains have patterns of cysteine residues involved in intrachain disulfide bonds that distinguish the four subfamilies: (1) biglycan, decorin, fibromodulin, and lumican; (2) keratocan and proline and arginine-rich end leucine-rich repeat protein (PRELP); (3) chondroadherin; and (4) epiphykan/PG-Lb and mimecan/osteoglycin. Biglycan may have two glycosaminoglycan chains—chondroitin sulfate or dermatan sulfate, or both—attached near the N-terminus through two closely spaced serine-glycine dipeptides. Decorin contains only one chondroitin sulfate or dermatan sulfate chain. Fibromodulin and lumican contain keratan sulfate chains linked to the central domain of the core protein and several sulfated tyrosine residues in the N-terminus. Negatively charged glycosaminoglycan side chains contribute to the fixed charge density of the matrix and, together with the highly anionic tyrosine-sulfation sites, permit multiple-site linkage between adjacent collagen fibrils, stabilizing the network. Decorin, the most extensively studied LRR proteoglycan, binds to collagens II, VI, XII, and XIV, and to fibronectin and thrombospondin. Biglycan, decorin, and fibromodulin bind transforming growth factor (TGF)- β and the epidermal growth factor receptor and may modulate growth, remodeling, and repair. PRELP and chondroadherin may regulate cell-matrix interactions through binding to syndecan and $\alpha 2\beta 1$ integrin.

Other Extracellular Matrix and Cell Surface Proteins

Several other noncollagenous matrix proteins may play important roles in determining cartilage matrix integrity. Cartilage oligomeric protein (COMP), a member of the thrombospondin family, is a disulfide-bonded, pentameric, 550 kD, calcium-binding protein that constitutes approximately 10% of the noncollagenous, nonproteoglycan protein in normal adult cartilage. COMP is located in the interterritorial matrix of adult articular cartilage, where it interacts with the COL3 and NC4 domains of type IX collagen that protrude from the fibril, stabilizing the collagen network. COMP is pericellular in the proliferating region of the growth plate, where it may have a role in cell-matrix interactions.⁴⁵ The cartilage matrix protein (or matrilin-1) and matrilin-3 are expressed in cartilage at certain stages of development and are present in tracheal cartilage. Matrilin-1 is present in the pericellular matrix of adult articular cartilage.^{46,47}

Tenascin-C, a glycoprotein that is regulated in development, is characteristic of nonossifying cartilage.⁴⁸ Similar to fibronectin, alternative splicing of tenascin-C mRNA gives rise to different protein products at different stages of chondrocyte differentiation. Both proteins are increased in OA cartilage and may serve specific functions in remodeling and repair. A splice variant of tenascin-C mRNA is found in chondrosarcomas.⁴⁹ The cartilage intermediate-layer protein (CILP) is expressed by chondrocytes in the middle to deep zones of articular cartilage as a precursor protein. When cleaved during secretion, CILP has structural similarities with nucleotide pyrophosphohydrolase, although it lacks the catalytic site, and it may play a role in pyrophosphate metabolism and calcification.^{50,51} Asporin is related to decorin and biglycan and, similar to those other LRR proteins, may interact with and sequester growth factors such as TGF- β .⁵²⁻⁵⁴ YKL-40/HC-gp39, also known as *chitinase 3-like protein 1*, is found only in the superficial zone of normal cartilage and stimulates proliferation of chondrocytes and synovial cells.⁵⁵ Chitinase 3-like protein 1 is induced by inflammatory cytokines and may function as a feedback regulator because it inhibits cytokine-induced cellular responses.^{56,57} Synthesis or release of these proteins or fragments is often increased in cartilage that is undergoing repair or remodeling, and they have been investigated as markers of cartilage damage in arthritis.^{31,32} A related member of the chitinase family, YKL-39, may be a more specific serum marker as a cartilage-derived autoantigen.^{58,59}

MORPHOLOGY, CLASSIFICATION, AND NORMAL FUNCTION OF CHONDROCYTES

Morphology

The characteristic feature of the chondrocyte embedded in cartilage matrix is its rounded or polygonal morphology. The exception occurs at tissue boundaries, such as the articular surfaces of joints, where chondrocytes may be flattened or discoid. Intracellular features, including a rough endoplasmic reticulum, a juxtanuclear Golgi apparatus, and deposition of glycogen, are characteristic of a synthetically active cell. Stockwell and Meachim⁶⁰ calculated that the cell density of full-thickness, human, adult, femoral condyle cartilage is maintained at $14.5 (\pm 3.0) \times 10^3$ cells/mm² from age 20 to 30 years. Because senescence of chondrocytes is known to occur with aging, it is logical to suppose that dead chondrocytes are replaced by mitosis. Mitotic figures are not observed, however, in normal adult articular cartilage.

The morphology, density, and synthetic activity of an adult chondrocyte vary according to its position within the different zones of articular cartilage.⁶¹⁻⁶³ In the region of highest cell density, the superficial zone, cells are flattened and are oriented parallel to the surface, along with the collagen fibers. Chondrocytes within the middle zone appear larger and more rounded and display a random distribution within the matrix, where the collagen fibers also are more randomly arranged. Chondrocytes in the deeper zones form columns that, along with the collagen fibers, are oriented perpendicular to the cartilage surface. Chondrocytes may exhibit different behaviors depending on their position

within the different layers, and these zonal differences in synthetic properties may persist in primary chondrocyte cultures.^{61,62} Chondrocyte volume in situ increases from the superficial through the deep zones and with the degree of cartilage degeneration.⁶ A study using confocal scanning laser microscopy of live, unfixed cartilage has revealed fine cytoplasmic processes extending from the cell bodies of 40% of chondrocytes.⁶⁴ These processes are proposed to permit interactions among chondrocytes and the cartilage matrix at near and remote sites. They are distinct from the cilia, which are observed by electron microscopy⁶⁵ but not by confocal scanning laser microscopy.⁶⁴

Classification: Cell Origin and Differentiation

Chondrocyte arises in the embryo from mesenchymal origin during *chondrogenesis*, which is the earliest phase of skeletal development involving mesenchymal cell recruitment, migration, and condensation and differentiation of mesenchymal chondroprogenitor cells.⁶⁶ As described in detail in Chapter 1, chondrogenesis results in the formation of cartilage anlagen, or templates, at sites where skeletal elements form. This process is controlled by cell-cell and cell-matrix interactions and by growth and differentiation factors that initiate or suppress cellular signaling pathways and transcription of specific genes in a temporospatial manner.

Vertebrate limb development is controlled by interacting patterning systems involving fibroblast growth factor (FGF), hedgehog, bone morphogenetic protein (BMP), and Wnt pathways. Wnt signaling, via the canonical β -catenin pathway and activation of TCF/Lef transcription factors, functions in a cell-autonomous manner to induce osteoblast differentiation and suppress chondrocyte differentiation in early chondroprogenitors.⁶⁷ During chondrogenesis, Wnt/ β -catenin acts at two stages: at low levels to promote chondroprogenitor differentiation, and later at high levels to promote chondrocyte hypertrophic differentiation and subsequent endochondral ossification.^{68,69} The transcription factor, Sry-type high-mobility group box 9 (Sox9), is an early marker of the differentiating chondrocyte that is required for the onset of expression of type II collagen, aggrecan, and other cartilage-specific matrix proteins, such as type IX collagen.⁷⁰ Two other members of the SOX family, L-Sox5 and Sox6, are not present in early mesenchymal condensations but are required during overt chondrocyte differentiation, forming heterodimers that induce transcription more efficiently than Sox9 by itself.⁷⁰ Expression of SOX proteins depends on signaling through mammalian homologs of *Drosophila* mothers against decapentaplegic (SMADs), which are functionally redundant and active in differentiating chondrocytes.⁷¹ A long form of c-Maf interacts with Sox9 at early stages to upregulate COL2A1 gene expression,⁷² whereas C/EBP β and C/EBP δ and AP-2 α may inhibit chondrocyte differentiation by blocking transcription of COL2A1, aggrecan (ACAN), and other cartilage-specific genes through direct or indirect mechanisms.⁷³⁻⁷⁵

In the embryonic or postnatal epiphyseal growth plates, upregulation of molecules that promote matrix remodeling and angiogenesis facilitates endochondral ossification, whereby bone replaces the calcified cartilaginous matrix in the hypertrophic zone (see Chapter 1). Differentiated

chondrocytes that remain in the reserve, or resting, zone become the cartilage elements in articular joints, or they can proliferate and undergo the complex process of terminal differentiation to hypertrophy marked by type X collagen. Indian hedgehog and parathyroid hormone–related protein transiently induce proliferation and repress differentiation, determining the number of cells that enter the hypertrophic maturation pathway.⁷⁶ The runt domain transcription factor, Runx2 (also known as *core binding factor* or Cbfa1), serves as a positive regulatory factor in chondrocyte maturation to the hypertrophic phenotype and subsequent osteogenesis.⁷⁷ Runx2 is expressed in the adjacent perichondrium and in prehypertrophic chondrocytes, but less in late hypertrophic chondrocytes, and is required for expression of type X collagen and other markers of terminal differentiation.⁷⁸

Numerous other transcription factors positively or negatively regulate chondrocyte terminal differentiation by controlling the expression or activity of Runx2.⁷⁹ BMP-induced Smad 1 and interactions between Smad 1 and Runx2 are required for the induction of chondrocyte hypertrophy. Because no SMAD site is present on the Runx2 promoter, it has been proposed that homeodomain proteins such as Dlx3 may activate Runx2 signaling in response to BMP-2 during endochondral ossification, whereas Dlx5, Dlx6, and Msx2 are known to inhibit Runx2-mediated activation of genes such as osteocalcin at later stages.⁸⁰ The homeodomain protein Nkx3.2, which is an early BMP-induced signal required at the onset of chondrogenesis, is a direct transcriptional repressor of Runx2 promoter activity.⁸¹ The bHLH factor Twist transiently inhibits Runx2 function and prevents premature osteoblast differentiation,⁸² whereas cooperation of the Groucho homolog Grg5 or the leucine zipper protein ATF4 with Runx2 promotes chondrocyte maturation.⁸³ Histone deacetylase 4 (HDAC4), which is expressed later in prehypertrophic chondrocytes, prevents premature chondrocyte hypertrophy by interacting with Runx2 and inhibiting its activity.⁸⁴ The hypoxia-inducible factor (HIF)-1 α is required for chondrocyte survival during hypertrophic differentiation, owing partially to its regulation of vascular endothelial cell growth factor (VEGF) expression.⁸⁵

The leucine zipper proteins Fra2, ATF2, and c-Maf are required for gene expression during late-stage hypertrophy (see for review, Goldring and Sandell⁷⁵). One major function of the chondrocyte is growth of the skeleton through increased cell proliferation, production of ECM, and cell volume through hypertrophy. After cessation of growth, the resting chondrocyte remains as part of the supporting structures in articular, tracheal, and nasal cartilages, indicating that the fate of a chondrocyte depends on origin and location (Figure 3-3).

Normal Function of the Adult Articular Chondrocyte

The mature articular chondrocyte embedded in its ECM is a resting cell with no detectable mitotic activity and a low rate of synthetic activity. Because articular cartilage is not vascularized, the chondrocyte must rely on diffusion from the articular surface or subchondral bone for exchange of nutrients and metabolites. Chondrocytes maintain active membrane transport systems for exchange of cations, including Na⁺, K⁺, Ca²⁺, and H⁺, whose intracellular

concentrations fluctuate with load and changes in the composition of the cartilage matrix.⁸⁶ The chondrocyte cytoskeleton is composed of actin, tubulin, and vimentin filaments, and the composition of these filament systems varies in the different cartilage zones.^{87,88}

Chondrocyte metabolism operates at low oxygen tension within the cartilage matrix, ranging from 10% at the surface to less than 1% in the deep zone. The consumption of oxygen by cartilage on a per-cell basis is only 2% to 5% of that in liver or kidney, although the amounts of lactate produced are comparable. Chondrocytes do not normally contain abundant mitochondria, energy metabolism depends strongly on the glucose supply, and the energy requirements may be modulated by mechanical stress.⁸⁹ Glucose serves as the major energy source for chondrocytes and as an essential precursor for glycosaminoglycan synthesis.⁹⁰ Facilitated glucose transport in chondrocytes is mediated by several distinct glucose transporter proteins (GLUTs) that may be constitutively expressed (GLUT3 and GLUT8) or cytokine inducible (GLUT1 and GLUT6).^{91,92} A proteomic study of chondrocytes identified 93 different intracellular proteins known to be involved in cell organization (26%), energy (16%), protein fate (14%), metabolism (12%), and cell stress (12%).⁹³ The relative expression of these proteins may determine the capacity of chondrocytes to survive in cartilage matrix and to modulate metabolic activity in response to environmental changes.

When cultured in a range of oxygen tensions between severe hypoxia (0.1% oxygen) and normoxia (21% oxygen), chondrocytes adapt to low oxygen tension by upregulating HIF-1 α . Hypoxia via HIF-1 α can stimulate chondrocytes to express GLUTs⁹² and angiogenic factors such as VEGF^{94,95} and numerous genes associated with cartilage anabolism and chondrocyte differentiation, including Sox9, TGF- β , and connective tissue growth factor.^{96,97} In the growth plate, hypoxia and HIF-1 α are associated with type II collagen production.⁹⁸ HIF-1 α is expressed in normal and OA articular cartilage, where it maintains tonic activity during physiologic hypoxia in the deeper layers associated with increased proteoglycan synthesis.⁹⁹ It is not completely degraded, however, as it is in other tissues, when normoxic conditions are applied.¹⁰⁰ Long-term systemic hypoxia (13%) may downregulate collagen and aggrecan gene expression in articular cartilage,¹⁰¹ whereas hyperoxia (55% oxygen) may increase the breakdown of cartilage collagens in articular cartilage in the presence of vascularized rheumatoid synovium.¹⁰² By modulating the intracellular expression of survival factors such as HIF-1 α , chondrocytes have a high capacity to survive in the avascular cartilage matrix and to respond to environmental changes. Findings that catabolic stress and inflammatory cytokines upregulate HIF-1 α suggest that it may serve as a survival factor in OA cartilage.^{99,103,104} More recent studies indicate that another hypoxia-inducible factor, HIF-2 α , can become activated by proinflammatory cytokines and stress in the avascular, hypoxic environment of articular cartilage.¹⁰⁵⁻¹⁰⁷

The chondrocyte maintains a steady-state metabolism secondary to equilibrium between anabolic processes and catabolic processes that results in the normal turnover of matrix molecules. In normal adult articular cartilage, the turnover of matrix components is low. The turnover of collagen has been estimated to occur with a half-life greater

Figure 3-3 Schematic representation of cellular phenotypes associated with developmental fates during condensation, chondrogenesis, chondrocyte proliferation, differentiation, and hypertrophy. Some of the regulatory factors active at different stages are listed to the left of the arrows. The major extracellular matrix genes are listed to the right of each cell type in which they are differentially expressed. BMP, bone morphogenetic protein; FGF, fibroblast growth factor; Hh, hedgehog; IGF, insulin-like growth factor; IL-1, interleukin-1; MMP, matrix metalloproteinase; PTHrP, parathyroid hormone-related protein; TGF- β , transforming growth factor- β ; VEGF, vascular endothelial growth factor; Wnt, wingless type.

than 100 years.^{108,109} In contrast, glycosaminoglycan constituents on the aggrecan core protein are more readily replaced; the half-life of aggrecan subfractions has been estimated to range from 3 to 24 years.¹¹⁰ Other cartilage ECM components, including biglycan, decorin, COMP, tenascins, and matrilins, incorporated previously into the matrix during development also may be synthesized by chondrocytes under low-turnover conditions. Regional differences in the remodeling activities of chondrocytes have been noted, however, and matrix turnover may be more rapid in the immediate pericellular zones.¹¹¹ The metabolic potential of these cells is indicated by their capacity to proliferate in culture and to synthesize matrix proteins after enzymatic release from the cartilage of even elderly individuals.

The complex composition of the articular cartilage matrix is more difficult for the chondrocyte to replicate if severe damage to the collagen network occurs. During initial stages of OA, chondrocytes *in vivo* respond to structural changes in the surrounding cartilage matrix by increasing cell proliferation and synthesis of matrix proteins,

proteinases, and anabolic and catabolic factors. The aberrant behavior of OA chondrocytes is reflected in the appearance of fibrillations; matrix depletion; cell clusters; and changes in quantity, distribution, or composition of matrix proteins.^{112,113} Evidence of phenotypic modulation is reflected in increases in collagens I and III¹¹⁴ and the appearance of the hypertrophic chondrocyte marker, type X collagen, and other chondrocyte differentiation genes, suggesting recapitulation of a developmental program.^{38,115} However, evidence reveals compensatory increases in type II collagen synthesis in deeper regions of the articular cartilage.¹¹²

Genomic and proteomic analyses of global gene expression in cartilage have confirmed increased *COL2A1* mRNA levels in early OA cartilage.¹¹⁶⁻¹¹⁸ Increased levels of factors such as BMP-2 and inhibin β A/activin, members of the TGF- β superfamily,^{117,119,120} and prostaglandins¹²¹ suggest the presence of anabolic responses. Nevertheless, Aigner and co-workers¹¹⁸ have shown that *COL2A1* expression is suppressed in upper zones of OA cartilage with progressing matrix destruction, whereas global *COL2A1* gene

expression is increased in late-stage OA cartilage compared with normal and early degenerative cartilage. The capacity of the adult articular chondrocyte to regenerate the normal cartilage matrix architecture is limited; the damage becomes irreversible, unless the destructive process is interrupted.

CULTURE MODELS FOR STUDYING CHONDROCYTE METABOLISM

Primary cultures of articular chondrocytes isolated from various animal and human sources have served as useful models for studying the mechanisms controlling responses to growth factors and cytokines.¹²²⁻¹²⁵ A challenge to researchers in cartilage biology is the maintenance of chondrocyte morphology and cartilage-specific gene expression during *in vitro* studies. In confluent primary monolayer cultures, chondrocytes maintain a rounded, polygonal morphology (Figure 3-4), but progressive loss of cartilage phenotype is seen with passage of time and after subculture. High-density cultures maintain the gene expression and synthesis of cartilage-specific matrix proteins until they are subcultured, although gene expression of type II collagen is generally more labile than that of aggrecan. During this loss of phenotype or dedifferentiation, chondrocytes lose the rounded, polygonal morphology and express some, but not

all, characteristics of the fibroblast phenotype, such as type I collagen. It is possible to expand cultures through a limited number of subcultures and to “redifferentiate” the cells in three-dimensional culture systems, in which chondrocytes regain morphology; cessation of proliferation is associated with increased expression of cartilage-specific matrix proteins. Alternatively, explant cultures of articular cartilage in which chondrocytes remain encased within their own ECM have been used as *in vitro* models to study cartilage biochemistry and metabolism, as described in the following section.

Articular Chondrocytes

Cartilage Explant (Organ) Cultures

Based on the pioneering work of Fell,¹²⁶ who showed that it was possible to maintain pieces of cartilage in culture, the explant culture system was developed to characterize chondrocyte function in cartilage from various species, including humans, at different ages. Early work in bovine cartilage established the mechanisms of biosynthesis of cartilage proteoglycans under the influence of different serum concentrations and determined the turnover rate whereby the chondrocyte could maintain the balance between anabolic and catabolic pathways.¹²⁷ Methods developed for measuring the proteoglycan content in cartilage and incorporation of ³⁵S-sulfate into newly synthesized proteoglycans are used widely as standard assays for assessing cartilage metabolism.¹²⁸ Cartilage organ cultures also maintain constant levels of type II collagen during several weeks of culture, along with the characteristic morphology and banding pattern of collagen fibrils. These cultures have been useful for studying the regulation of cartilage matrix synthesis and degradation by proteinases, inflammatory cytokines, retinoic acid, and anabolic growth factors.

Monolayer Cultures

Primary monolayer cultures of chondrocytes isolated from young animals that maintain the cartilage-specific phenotype at least throughout primary culture are easily obtained and have been used widely to assess differentiated chondrocyte functions. When chondrocytes are isolated from their matrix and cultured in monolayer, they adhere to the culture dish and readily respond to serum growth factors that stimulate proliferation of normally quiescent cells. Freshly isolated human articular or costal chondrocytes express cartilage-specific type II collagen and continue to do so for several days to weeks in primary monolayer culture.^{129,130} In addition to cartilage-specific collagens and aggrecan, chondromodulin and protein S-100 are useful markers expressed in primary chondrocyte cultures.¹³¹⁻¹³³ Identification of cell surface markers that determine chondrogenic capacity enables the enrichment of subpopulations for further characterization.¹³⁴

Early attempts to culture chondrocytes from various animal and human sources were frustrated by the tendency of these cells to acquire a fibroblast-like morphology associated with the appearance of type I collagen synthesis.^{3,124} When plated at high density, the cells maintain a polygonal, although flattened, morphology. At low plating densities,

Figure 3-4 Morphology of human articular chondrocytes grown in monolayer culture on plastic. Chondrocytes were isolated from articular cartilage and cultured in growth medium containing 10% fetal calf serum until confluent. The cultures were changed to serum-free defined medium, interleukin-1 β (IL-1 β) was added the next day, and incubation was continued for 24 hours. **A**, Untreated chondrocytes display the characteristic cobblestone morphology. **B**, IL-1 β -treated cultures respond with a dramatic morphologic change.

with prolonged culture, and on expansion in serial subculture, the cells gradually assume a more elongated, “fibroblast-like” morphology. Early work suggested that this change in morphology is associated with loss of phenotype, whereby the synthesis of cartilage-specific matrix molecules, such as type II collagen and aggrecan, decreases or disappears. This “dedifferentiated phenotype,” which has been described so far only in vitro, is marked by the appearance of synthesis of type I and type III collagens, and it can be accelerated by plating the cells at low densities or by treating with cytokines such as interleukin (IL)-1 or retinoic acid. Lack of correlation between cell shape and chondrocyte phenotype has been reported. Dedifferentiation of chondrocytes in monolayer culture seems to be associated, however, with increased expression of genes involved in cell proliferation, such as cyclin D1.¹³¹ The substrate on which chondrocytes are plated can influence the differentiation capacity of articular chondrocytes.¹³⁵

The use of chondrocytes of adult human origin in studies related to the pathogenesis of joint disease has been problematic because the source of the cartilage cannot be controlled, sufficient numbers of cells are not readily obtained through random operative procedures, and the phenotypic stability of adult human chondrocytes is lost more quickly on expansion in serial monolayer cultures than in cells of juvenile human or embryonic or postnatal animal origin. Serum-free defined media of varying compositions, but usually including insulin, have been used, frequently in combination with monolayer and other culture systems, as mentioned in the following section.^{136,137}

Three-Dimensional Culture Systems

Early studies showed that phenotype could be maintained if isolated chondrocytes are placed in suspension cultures in spinner flasks or in dishes coated with nonadherent substrates.^{3,124} Freshly isolated or subcultured chondrocytes also can be embedded in three-dimensional matrices, such as collagen gels or sponges,^{138,139} agarose,^{140,141} or alginate.^{142,143} In these three-dimensional matrices, chondrocytes have a normal spherical shape, synthesize and secrete abundant cell-associated ECM components, and may maintain phenotypic stability for several months. Because articular chondrocytes are unable to proliferate in suspension or three-dimensional culture, expansion in monolayer culture followed by transfer to alginate culture, for example, has been used as a strategy to obtain sufficient numbers of differentiated chondrocytes for study. After prolonged culture in monolayer, however, dedifferentiated chondrocytes may lose irreversibly their chondrogenic potential.¹⁴⁴ The high-density pellet culture system, originally developed to study growth plate hypertrophy, has been used as a three-dimensional model because it permits articular chondrocytes to deposit a well-organized ECM containing type II collagen and aggrecan.^{134,145,146} Articular chondrocytes in micromass culture show *phenotypic plasticity* comparable with that of mesenchymal stem cells undergoing chondrogenesis, by recapitulating aspects of chondrocyte hypertrophy.^{147,148} Isolated chondrons containing one or more chondrocytes within a capsule of pericellular matrix have been used for in vitro studies of chondrocyte metabolism within a three-dimensional environment.¹⁴⁹

Prehypertrophic and Hypertrophic Chondrocytes: Models of the Growth Plate and Terminal Differentiation

Tissues or cells from embryonic or young animals at specific developmental stages or with different developmental fates have been used widely to recapitulate in vitro the transitional stages of chondrogenesis, chondrocyte hypertrophy, and endochondral ossification.^{3,124} A common feature of these models is the requirement for deposition of a collagenous matrix by sufficient numbers of cells after cessation of proliferation of chondrogenic cells in high-density micromass, pellet, or three-dimensional matrix cultures. Epiphyseal chondrocytes isolated from the long bones of postnatal immature rats and rabbits and cultured at high density progress through a differentiation pathway that mimics the transition from a type II collagen-producing, proliferating chondrocyte phenotype to the terminally differentiated type X collagen-producing hypertrophic phenotype associated with growth plate formation and endochondral ossification. Alkaline phosphatase, osteocalcin, and osteopontin have also been used as markers of terminal differentiation.

The pellet and micromass culture systems have been used widely to study terminal differentiation and hypertrophy because they mimic the distribution of cells within the growth plate, and they are sufficiently organized to permit calcification in situ.¹⁴⁸ Arrest of cell proliferation and activation of type X collagen expression occur when the serum concentration is reduced from 10% to 2% or lower. Insulin-like growth factor (IGF)-1 or insulin added in serum-free medium or as a constituent of serum seems to be a universal basal requirement in these culture systems. Ascorbic acid and treatments such as thyroxine 1,25-dihydroxyvitamin D₃, retinoic acid, or dexamethasone promote terminal differentiation in vitro. Ectopic matrix mineralization also may require a phosphate donor such as β -glycerophosphate. In contrast, certain BMPs alone or in the presence of ascorbic acid may induce hypertrophy and mineralization in the absence of other additives, if the appropriate progenitor cell population is used.

Chondrocyte Cell Lines

Because primary human chondrocytes in monolayer cultures maintain phenotype only until they are passaged, researchers have attempted to develop chondrocyte cell lines with variable success. Immortalization of chondrocytes from mice, rats, and other species with viral oncogenes has generated cell lines with high proliferative capacities and at least some differentiated chondrocyte properties.¹⁵⁰⁻¹⁵² Attempts to generate cell lines that can undergo chondrogenesis and terminal differentiation to the hypertrophic phenotype have been more successful because of the availability and plasticity of progenitor cell populations. Cells derived from the ribs of transgenic mice harboring the temperature-sensitive mutant of simian virus 40 (SV40) large T antigen (TA_g) are able to undergo hypertrophic differentiation,^{153,154} and bone marrow-derived mesenchymal stem cells derived from these mice contain osteogenic, adipogenic, myogenic, and chondrogenic progenitor cells. Several chondrogenic cell lines from mice or rats, including

ATDC5, C3H10T1/2, RCJ3.1, CK2, and C1, are now used widely in the field, as reviewed by Johnstone and colleagues.¹⁵⁵

Human chondrosarcoma cell lines express some aspects of the chondrocyte phenotype but are tumorigenic.^{156,157} Stable transduction of SV40-TAg using plasmid or retroviral vectors has yielded immortalized human chondrocyte cell lines that are useful for studying the regulation of gene expression under defined conditions, but they do not produce sufficient quantities of matrix proteins to form cartilage matrix owing to high rates of proliferation.¹⁵⁸ Human articular chondrocyte cell lines also have been established using temperature-sensitive SV40-TAg,¹⁵⁹ the human papillomavirus type 16 early function genes *E6* and *E7*,¹⁶⁰ and telomerase,¹⁶¹ although those derived from adult tissues have low proliferative capacity. A general observation is that phenotypic stability of immortalized chondrocytes is lost during serial subculture in monolayer but can be restored by transfer to three-dimensional culture in alginate¹⁵⁹ or hyaluronan,¹⁶⁰ or to suspension culture in poly-2-hydroxyethyl methacrylate-coated dishes.¹⁶¹ Immortalized chondrocytes may continue to proliferate in three-dimensional culture, however, and if the scaffold cannot be remodeled, necrotic clusters form. Studies to date indicate that mature chondrocytes removed from the ideal cartilage environment *in vivo* are incapable of replicating normal phenotype *in vitro*; the perfect chondrocyte culture model that reproduces the normal cartilage environment has yet to be fabricated, as confirmed by gene profiling studies.^{162,163}

INTERACTIONS OF CHONDROCYTES WITH THE EXTRACELLULAR MATRIX

Chondrocytes *in vivo* respond to structural changes in the cartilage ECM. The ECM not only provides a framework for chondrocytes suspended within it, but its constituents interact with cell surface receptors and provide signals that regulate many chondrocyte functions.^{88,164,165}

Integrins

The most prominent of the ECM receptors are the integrins, which bind specifically with different cartilage matrix components and induce the formation of intracellular signaling complexes that regulate cell proliferation, differentiation, survival, and matrix remodeling. Integrins also may serve as mechanoreceptors and may mediate responses to normal and abnormal loading of cartilage.¹⁶⁶⁻¹⁶⁸ Chondrocytes express many different integrins that interact with cartilage ECM ligands, although most are not specific to this cell type.^{35,88,165,169} They include integrins that are receptors for collagen ($\alpha1\beta1$, $\alpha2\beta1$, $\alpha3\beta1$, $\alpha10\beta1$), fibronectin ($\alpha5\beta1$, $\alpha v\beta3$, $\alpha v\beta5$), and laminin ($\alpha6\beta1$). The integrin $\alpha1\beta1$ has broader ligand specificity than the other collagen-binding integrins and mediates chondrocyte adhesion to pericellular type VI collagen and to the cartilage matrix protein, matrilin-1. The $\alpha2\beta1$ integrin also binds to chondroadherin. The αv -containing integrins bind to vitronectin and osteopontin, in addition to serving as alternative fibronectin receptors. The $\alpha5\beta1$ and $\alpha v\beta3$ integrins serve as receptors for different conformations of COMP.¹⁷⁰

Because $\alpha1\beta1$, $\alpha2\beta1$, and $\alpha10\beta1$ are receptors for cartilage-specific type II collagen, there is great interest in determining whether they mediate differential responses of chondrocytes to changes in the ECM resulting from normal loading or pathologic changes.¹⁶⁶⁻¹⁶⁸ The $\alpha5\beta1$ integrin is the prominent integrin in human adult articular cartilage. Depending on the method of analysis, adult chondrocytes also express $\alpha1\beta1$ and $\alpha v\beta5$ integrins accompanied by weaker expression of $\alpha3\beta1$ and $\alpha v\beta3$. Normal adult articular chondrocytes express little or no $\alpha2\beta1$, whereas expression of $\alpha2\beta1$ and $\alpha3\beta1$ integrins is associated with a proliferative phenotype, as in fetal chondrocytes and in chondrosarcoma and chondrocyte cell lines.^{171,172} In growth plate chondrocytes, $\alpha5\beta1$, $\alpha v\beta5$, and $\alpha10\beta1$ are important for joint formation, chondrocyte proliferation, hypertrophy, and survival.¹⁷³⁻¹⁷⁷ Knockout of $\beta1$ integrin results in severe growth plate abnormalities and chondrodysplasia,¹⁷⁸ whereas $\alpha1$ integrin knockout mice develop OA without growth plate abnormalities.¹⁷⁹

Cellular binding to immobilized ECM proteins or integrin receptor aggregation with activating antibodies can promote numerous intracellular signaling events.⁸⁸ As in other cell types, integrin signaling is mediated by interaction with intracellular protein tyrosine kinases, such as pp125 focal adhesion kinase (FAK) and *pyk2Pyk2*, which interact with the integrin cytoplasmic tail and induce a conformational change in the receptor subunits. Changes in organization of the cytoskeleton are associated with the formation of integrin signaling complexes, which contain scaffolding proteins such as talin, paxillin, and α -actinin, in addition to FAK and the integrin-linked kinase (ILK). Mice lacking ILK in cartilage display chondrodysplasia, a phenotype similar to that of cartilage-specific $\beta1$ integrin knockout mice.^{178,180} Other signaling kinases, such as Src, Ras/Raf, Sos, and Mek family members, may be associated with integrin signaling complexes and mediate downstream signaling cascades in a cell type-specific and ligand-specific manner.

Cooperative signaling among integrins and growth factors is a fundamental mechanism in the regulation of cellular functions. Integrin aggregation and receptor occupancy enhance phosphorylation of growth factor receptors and activation of mitogen-activated protein kinases (MAPKs) in many cell types. The anchorage-dependent mitogenic response to growth factors is thought to be due to synergy between integrin and growth factor signaling. Induction of chondrocyte proliferation by FGF requires fibronectin binding to $\alpha5\beta1$ integrin.¹⁷⁵ The $\beta1$ integrin subunit also interacts with the IGF-I receptor on treatment of chondrocytes with IGF-I.¹⁸¹ Fibronectin increases FGF-stimulated and IGF-I-stimulated proteoglycan synthesis in chondrocytes, and nitric oxide, which disrupts focal adhesion signaling complexes, inhibits this process.¹⁸² Type II collagen increases TGF- β -induced type II collagen and aggrecan gene expression through a feedback mechanism that is mediated by $\beta1$ integrin.¹⁸³

The primary fibronectin receptor, $\alpha5\beta1$, may play a role in cartilage degradation by binding to fibronectin fragments that upregulate matrix metalloproteinases (MMPs), such as MMP-3 and MMP-13.¹⁸⁴⁻¹⁸⁶ Extensive studies in cultured chondrocytes have shown that $\alpha5\beta1$ is crucial in the hyperpolarization response to mechanical load.¹⁶⁷ Normal

chondrocytes use $\alpha 5 \beta 1$ as a mechanoreceptor, and subsequent to activation of the integrin-signaling cascade by mechanical stimulation is secretion of IL-4, which acts in an autocrine manner via the janus activating kinase (JAK)/signal transducer and activator of transcription (STAT) pathway to increase aggrecan mRNA and decrease MMP-3 mRNA levels.¹⁸⁷

Chondrocyte adhesion to fibronectin or binding to fibronectin fragments increases the production of cytokines, such as IL-1 β , tumor necrosis factor (TNF), IL-6, and granulocyte-macrophage colony-stimulating factor. Synergies between fibronectin/ $\alpha 5 \beta 1$ and IL-1 β have been shown in chondrocytes.^{188,189} OA chondrocytes respond to $\alpha 5 \beta 1$ ligation by production of IL-1 β and other proinflammatory mediators, whereas $\alpha v \beta 3$ integrin ligation attenuates these responses.¹⁸⁸ Nevertheless, good evidence suggests that fibronectin fragments or blocking antibodies to $\alpha 2 \beta 1$ and $\alpha 5 \beta 1$ integrins can directly stimulate signaling via extracellular signal-regulated kinase (ERK)-1 or ERK-2, c-Jun N-terminal kinase (JNK), and p38 MAPK in chondrocytes and can increase MMP-13 production independent of autocrine production of IL-1 β .¹⁸⁵ This response requires reactive oxygen species.¹⁹⁰ Collagen binding to $\alpha 1 \beta 1$ and $\alpha 2 \beta 1$ integrins also results in activation of distinct signaling pathways and may lead to opposite cellular responses.¹⁹¹ Downregulation of IL-1 β -induced responses by dynamic compression is mediated by integrins.¹⁹² The specificity of the response may depend on the relative expression of α -integrin subunits on the chondrocyte cell surface.

Other Cell Surface Receptors in Chondrocytes

Other integral membrane proteins found in chondrocytes include cell determinant 44 (CD44), anchorin CII, and syndecans.¹⁹³ CD44, a receptor for hyaluronan, binds collagen and fibronectin. Through specific interactions with hyaluronan, CD44 has a role in assembly, organization, and maintenance of the chondrocyte pericellular matrix.¹⁹⁴ In chondrocyte cultures, assembly of a newly synthesized pericellular matrix can be prevented or reversed by incubation with hyaluronan hexasaccharides or with a CD44 monoclonal antibody. CD44 expression is upregulated in chondrocytes in articular cartilage from RA patients and in experimental OA.¹⁹⁵ Hyaluronan binding to CD44 increases MMP-13 and nitric oxide production by chondrocytes.¹⁹⁶ Although blocking of CD44 has no effect on attachment of chondrocytes to a cut cartilage surface, recent evidence indicates that CD44 mediates the expression of MMP-1, MMP-2, MMP-9, and MMP-13; MMP-specific cleavage of type II collagen; and the production of nitric oxide induced by the heparin-binding fibronectin fragment in articular cartilage.^{197,198} Because fibronectin fragments and IL-1 β enhance CD44 expression in chondrocytes, cell-matrix interactions mediated by such cell surface receptors represent alternative mechanisms for cartilage damage in joint disease. During joint disease, CD44-mediated co-internalization with hyaluronic acid may be one important mechanism for the elimination of residual aggrecan fragments after extracellular degradation.¹⁹⁹ Aggrecanase-mediated depletion of proteoglycan does not require CD44, however.²⁰⁰

Anchorin V, also known as *annexin CII*, is a 34 kD integral membrane protein that binds type II collagen and shares extensive homology with the calcium-binding proteins calpactin and lipocortin.^{201,202} Annexins II, V, and VI have been detected in chondrocytes, where they likely play roles in physiologic mineralization of skeletal tissues and in pathologic mineralization of articular cartilage.²⁰³ Annexin V was first detected in chick cartilage and was described as a type II collagen-binding protein that anchors chondrocytes to the ECM. In growth plate chondrocytes, annexins are required for calcium ion uptake and subsequent mineralization. Annexin V antibodies block chondrocyte attachment to immobilized type II collagen more effectively than integrin antibodies, but not to a cut cartilage surface, where the N-terminal collagen-binding site may not be exposed.¹⁹³ In contrast to integrins, annexin V binds to the N-telopeptide of type II collagen, but not to triple-helical fragments.²⁰⁴

Syndecans have important roles during cartilage development and homeostasis. Syndecans link to the cell surface via glycosyl phosphatidylinositol and bind growth factors, proteinases and inhibitors, and matrix molecules through heparan sulfate side chains on the extracellular domain. Syndecan-1, syndecan-3, and syndecan-4 are upregulated in human and mouse OA.²⁰⁵⁻²⁰⁷

In contrast to integrins, which bind collagen fragments, discoidin domain receptor 2 (DDR2) binds specifically to type II and X collagen fibrils, leading to activation of its integral receptor tyrosine kinase.^{208,209} DDR2 is upregulated in OA cartilage and induces specifically the expression of MMP-13 associated with cleavage of type II collagen.²¹⁰ Studies have shown that the serine proteinase, high temperature requirement A1 (HTRA1), which is increased in the articular cartilage of mouse models of OA and human OA cartilage,²¹¹⁻²¹³ is responsible for disrupting the pericellular matrix, which is composed of matrilin-3, fibronectin, biglycan, fibromodulin, COMP, and collagen VI, thereby exposing DDR2 to activation by type II collagen in fibrillar form.²¹³

ANGIOGENIC AND ANTIANGIOGENIC FACTORS

Adult articular cartilage is among the few avascular tissues in mammalian organisms; this property and the presence of angiogenesis inhibitors make it resistant to vascular angiogenesis and invasion by inflammatory and neoplastic cells. In conditions in which extensive remodeling of ECM occurs, as in arthritis, the cartilage becomes susceptible to invasion by vascular endothelial and mesenchymal cells from the synovium and subchondral bone.²¹⁴ In OA, upregulation of angiogenic factors may contribute to ingrowth of blood vessels, tidemark advancement, and cartilage calcification in the deep zone. In RA, ingrowth of blood vessels and synovial pannus into cartilage contributes to degradation of the cartilage matrix. Troponin I, MMP inhibitors, chondromodulin-I, and endostatin, a 20 kD proteolytic fragment of type XVIII collagen, all function as endogenous angiogenic inhibitors.²¹⁵⁻²¹⁸ VEGF, which is an essential mediator of angiogenesis during endochondral ossification (see Chapter 1), is induced by hypoxia and

mechanical overload.^{219,220} In OA, in which abnormal biomechanics and joint effusions cause severe hypoxia, chondrocytes may produce VEGF, inducing angiogenesis at the chondro-osseous junction and contributing to cartilage destruction.^{221,222}

Intercellular adhesion molecules also contribute to angiogenesis. These include vascular cell adhesion molecule-1 (VCAM-1) and intercellular adhesion molecule-1 (ICAM-1), which are expressed by human articular chondrocytes and synovial and endothelial cells. Their function on chondrocytes may not be significant, however, unless damage to the matrix permits cell-cell interactions.²²³ VCAM-1, VEGF, FGF, and TNF contribute to angiogenesis during synovitis and to activation of chondrocytes during cartilage degradation.^{224,225} In RA, VEGF expression may be upregulated by inflammatory cytokines in chondrocytes and synovial cells and by hypoxia.^{224,225} The importance of this mechanism is supported by findings in *Vegfb* knockout mice, which are protected against synovial angiogenesis in experimental inflammatory models.²²⁶

ROLES OF GROWTH AND DIFFERENTIATION (ANABOLIC) FACTORS IN NORMAL CARTILAGE METABOLISM

Growth and differentiation factors generally are considered positive regulators of homeostasis of mature articular cartilage because of their capacity to stimulate chondrocyte anabolic activity and, in some cases, inhibit catabolic activity (see Chapter 1).²²⁷ The best characterized anabolic factors in the context of their production and action in articular cartilage include IGF-I and members of the FGF and TGF- β /BMP families.²²⁸⁻²³² Many of these factors also regulate chondrogenesis and endochondral ossification during skeletal development.⁶⁶ In adult cartilage, their expression declines with age—a risk factor for OA—and their activities are downregulated.²²⁷

Insulin-like Growth Factor

IGF-I, also known as *somatomedin C*, was first discovered as a serum factor controlling sulfate incorporation by articular cartilage in vitro and was later found to have the specific capacity to stimulate or maintain chondrocyte phenotype in vitro by promoting the synthesis of type II collagen and aggrecan. IGF-I is a competence factor for cell proliferation that is categorized more appropriately as a differentiation factor because its limited mitogenic activity seems to depend on the presence of other growth factors, such as FGF-2, a progression factor.¹⁴² IGF-I is considered an essential mediator of cartilage homeostasis through its capacity to stimulate proteoglycan synthesis, promote chondrocyte survival, and oppose the activities of catabolic cytokines in cooperation with other anabolic factors such as BMP-7.^{143,233-235} IGF-I and insulin can activate the cell surface IGF-I tyrosine kinase receptor or the type I insulin receptor at concentrations proportional to their binding affinities.²²⁷

Specific IGF-binding proteins (IGFBPs) that do not recognize insulin also regulate IGF-I activity. Chondrocytes at

different stages of differentiation express IGF-I and IGF receptors and different arrays of IGFBPs, providing a unique system by which IGF-I can exert different regulatory effects on these cells. IGFBP-2 seems to be a positive regulator in chondrocytes because its induction by TGF- β or estrogen is associated with increased proteoglycan synthesis.²³⁶ Binding of IGFBP-3 to IGF-I is thought to regulate negatively the anabolic functions of IGF-I, although IGFBP-3 may directly inhibit chondrocyte proliferation in an IGF-independent manner.

In OA cartilage, the normal anabolic function of IGF-I may be disrupted because chondrocytes from animals with experimental arthritis and from patients with OA are hyporesponsive to IGF-I, despite normal or increased IGF-I receptor levels. This hyporesponsiveness has been attributed to increased levels of IGFBPs that may interfere with IGF-I actions.^{237,238} Disturbances in the balance of IGF-I to IGFBPs that have been reported in OA and RA joints may contribute to defective chondrocyte responses to IGF-I.²³⁷⁻²⁴⁰ Small-molecule inhibitors of IGF-I/IGFBP interactions that could restore IGF-I-dependent proteoglycan synthesis in cartilage have been proposed for treatment of OA.²³⁵ Although IGF-I can oppose the effects of inflammatory cytokines that promote cartilage degradation and inhibit proteoglycan synthesis,²⁴¹ these cytokines increase the production of IGFBP-3 by chondrocytes.²⁴² Overproduction of nitric oxide may contribute to IGF-I resistance by chondrocytes through disruption of integrin signaling, reduction of phosphorylation of the IGF-I receptor, stimulation of cyclic guanosine monophosphate production, or suppression of mitochondrial oxidative metabolism.^{234,243-246} More recent evidence indicates that suppressor of cytokine signaling 3 (SOCS3) acts as a negative feedback regulator during IGF-I desensitization in the absence of nitric oxide by inhibiting insulin receptor substrate-1 phosphorylation.²⁴⁷

Fibroblast Growth Factor

Members of the FGF family, including FGF-2, FGF-4, FGF-8, FGF-9, FGF-10, and FGF-18, together with the FGF receptors, FGFR1, FGFR2, and FGFR3, coordinate patterning and cell proliferation during chondrogenesis and endochondral ossification in embryonic and postnatal growth plates.²⁴⁸ The most extensively studied is FGF-2, or basic FGF, which is a potent mitogen for adult articular chondrocytes,²³¹ but findings on its effects on the synthesis of cartilage matrix are contradictory, showing stimulation, inhibition, or no effect on proteoglycan synthesis.^{142,249}

Early studies suggested that low concentrations of FGF-2 could stimulate chondrocyte mitogenesis and proteoglycan synthesis, whereas high concentrations might have opposite effects.²⁵⁰ More recent studies showing that FGF-2 stored in the adult cartilage matrix is released with mechanical injury or with loading suggest a mechanism for modulating chondrocyte proliferation and anabolic activity.^{251,252} Although FGF-2 and FGF-9 stimulate the expression of Sox9 and increase the activity of the Sox9-dependent, chondrocyte-specific enhancer in the type II collagen gene,^{253,254} FGF-2 can inhibit the anabolic activities of IGF-I and osteogenic protein-1 (OP-1) in vitro.¹⁴² FGF-9 and FGF-18 increase matrix synthesis by mature chondrocytes.²⁵⁵⁻²⁵⁸ A study

showed that FGF-18 promotes cartilage repair in a rat meniscal tear model of OA.²⁵⁹ FGF-2 stimulates, whereas IGF-I inhibits, expression of the matrix Gla protein, which is a marker of chondrocyte survival during endochondral ossification.^{260,261} Therefore FGFs and FGF receptors are important regulators of cartilage homeostasis during prenatal and postnatal life.

TGF- β /BMP Superfamily

Activities of the TGF- β /BMP superfamily in the skeleton were first discovered by Marshall Urist as constituents of demineralized bone that induced new bone formation when implanted into extraskeletal sites in rodents.²⁶² These bioactive morphogens subsequently were extracted, purified, and cloned and were found to regulate the early commitment of mesenchymal cells to chondrogenic and osteogenic lineages during cartilage development and endochondral bone formation (Table 3-2). The TGF- β /BMP superfamily includes activins, inhibins, müllerian duct inhibitory substance, and nodal, glial-derived neurotrophic factor, OP-1 (or BMP-7), and growth differentiation factors (GDFs), also called *cartilage-derived morphogenetic proteins* (CDMPs).²⁶³ In addition to regulating cartilage condensation and chondrocyte differentiation, members of this superfamily play key roles in site specification and cavitation of synovial joints (see Chapter 1) and in the development of other organ systems. Many of these factors, including BMP-2, BMP-6, BMP-7, BMP-9, TGF- β , and CDMP-1, are able to induce chondrogenic differentiation of mesenchymal progenitor cells in vitro. They also may have direct effects on mature articular chondrocytes in vivo and in vitro.

Table 3-2 Bone Morphogenetic Protein Superfamily

Bone Morphogenetic Protein	Other Names	Potential Function
BMP-2	BMP-2A	Cartilage and bone morphogenesis
BMP-3	Osteogenin, GDF-10	Bone formation
BMP-4	BMP-2B	Cartilage and bone morphogenesis
BMP-5		Bone morphogenesis
BMP-6	Vegetal-related-1 (Vgr-1)	Cartilage hypertrophy
BMP-7	Osteogenic protein-1 (OP-1)	Cartilage and bone morphogenesis
BMP-8	Osteogenic protein-2 (OP-2)	Bone morphogenesis
BMP-9	GDF-2	Cartilage morphogenesis
BMP-10		Unknown
BMP-11	GDF-11	Unknown
BMP-12	GDF-7, CDMP-3	Cartilage morphogenesis
BMP-13	GDF-6, CDMP-2	Cartilage morphogenesis
BMP-14	GDF-5, CDMP-1	Cartilage morphogenesis

CDMP, cartilage-derived morphogenetic protein; GDF, growth and differentiation factor.

Transforming Growth Factor- β

TGF- β was named on the basis of its discovery as a factor that could transform cells to grow in soft agar. TGF- β is not a potent inducer of chondrocyte proliferation, however; rather, it controls early mesenchymal cell condensation, as well as chondrocyte differentiation at early and late stages of chondrogenesis and endochondral ossification (see Chapter 1). Both inhibition and stimulation of the synthesis of aggrecan and type II collagen by TGF- β have been observed in vitro. TGF- β , by itself, cannot rescue the type II collagen phenotype, however, when cells have undergone dedifferentiation during serial passaging. Levels of TGF- β measured in synovial fluids of OA and RA patients may reflect anabolic processes in cartilage and other joint tissues. TGF- β may promote anabolism by inducing the expression of tissue inhibitors of MMP (TIMP).

Nevertheless, TGF- β 1, TGF- β 2, and TGF- β 3 generally are considered as potent stimulators of proteoglycan and type II collagen synthesis in primary chondrocytes and cartilage explants in vitro.²⁶⁴ Microarray analysis of chondrocytes in vitro indicates that TGF- β is able to counteract the expression of numerous IL-1-induced genes involved in cartilage injury.²⁶⁵ Although intra-articular injection of TGF- β stimulates proteoglycan synthesis and limits cartilage damage in inflammatory arthritis models, injection or adenovirus-mediated delivery of TGF- β 1 may result in side effects in joint tissues, such as osteophyte formation, swelling, and synovial hyperplasia.^{266,267} Administration of agents that block TGF- β activity, such as the soluble form of TGF- β RII, inhibitory SMADs, or the physiologic antagonist, latency-associated peptide-1, increases proteoglycan loss and cartilage damage in an experimental model of OA.^{268,269} A more recent finding that TGF- β induces expression of ADAMTS (a disintegrin and metalloproteinase [ADAM family] with thrombospondin-1 domains)-4 in primary human chondrocytes and promotes the degradation of aggrecan suggests that it may be involved in normal turnover of proteoglycans in mature cartilage.²⁷⁰ Findings that IL-1 differentially regulates inhibitory SMADs and transcriptional mediators of TGF- β and BMP signaling,²⁷¹ and decreases TGF- β signaling associated with loss of a protective effect of TGF- β during OA progression,²⁷² suggest that the balance of inhibitory and stimulatory molecules determines cartilage homeostasis.

Bone Morphogenetic Proteins

BMPs constitute a large subclass of the TGF- β superfamily essential for normal appendicular skeletal and joint development.^{228,263,273} The isolation and cloning of the first BMP family members from bone prompted a search for cartilage-derived BMPs, or CDMPs—CDMP-1, CDMP-2, and CDMP-3—which are classified as GDF-5, GDF-6, and GDF-7. The BMPs may be divided into four distinct subfamilies based on the similarity of primary amino acid sequences: (1) BMP-2 and BMP-2B (BMP-4), which are 92% identical in the 7-cysteine region; (2) BMP-3 (osteogenin) and BMP-3B (GDF-10); (3) BMP-5, BMP-6, BMP-7 (OP-1), BMP-8 (OP-2), BMP-9 (GDF-2), BMP-10, and BMP-11 (GDF-11); and (4) BMP-12 (GDF-7 or CDMP-3), BMP-13 (GDF-6 or CDMP-2), BMP-14 (GDF-5 or

CDMP-1), and BMP-15. BMP-1 is not a member of this family but is an astacin-related MMP that cleaves the BMP inhibitor chordin and acts as a procollagen C-proteinase.²⁷⁴

Several BMPs, including BMP-2, BMP-7 (OP-1), and GDF-5/CDMP-1, can stimulate differentiation of mesenchymal precursors into chondrocytes and promote the differentiation of hypertrophic chondrocytes.^{275,276} BMP-2, BMP-4, BMP-6, BMP-7, BMP-9, and BMP-13 can enhance the synthesis of type II collagen and aggrecan by articular chondrocytes in vitro.^{230,277,278} In addition, BMP-7 reverses many of the catabolic responses induced by IL-1 β , including induction of MMP-1 and MMP-13, downregulation of TIMP, and downregulation of proteoglycan synthesis in primary human articular chondrocytes.²³⁰ CDMP-2 is found in articular cartilage, skeletal muscle, placenta, and hypertrophic chondrocytes of the epiphyseal growth plate. CDMP-1 and CDMP-2 maintain the synthesis of type II collagen and aggrecan in mature articular chondrocytes, although they are less effective initiators of chondrogenesis than other BMPs in early progenitor cell populations in vitro.²⁷⁷

BMP-7 is expressed in mature articular cartilage and is possibly the strongest anabolic stimulus for adult chondrocytes in vitro because it increases aggrecan and type II collagen synthesis more strongly than IGF-I.²³⁰ BMP-2 also is expressed in normal and OA articular cartilage,¹²⁰ and it is a molecular marker, along with type II collagen and FGF receptor 3 (FGFR3), for the capacity of adult articular chondrocyte cultures to form stable cartilage in vivo.¹⁴¹ BMP-2, BMP-7, and BMP-9 are able to oppose many of the detrimental effects of IL-1 on chondrocyte metabolism in vitro and in vivo.^{276,279} BMP-7 can prevent retinoic acid-induced dedifferentiation of articular chondrocytes.²⁸⁰ BMPs have pleiotropic effects in vivo, however, acting in a concentration-dependent manner. While initiating chondrogenesis in the limb bud, they generally set the stage for bone morphogenesis (see Chapter 1). Several BMPs also are true morphogens for other tissues, such as kidney, eye, heart, and skin.

Receptors, Signaling Molecules, and Antagonists That Mediate Chondrocyte Responses to Growth and Differentiation Factors

Major pathways activated by the growth and differentiation factors discussed earlier involve members of the ERK1/2, p38 MAPK, and phosphatidylinositol-3'-kinase (PI-3K)/v-akt murine thymoma viral oncogene homolog (AKT) pathways.²⁸¹ As in other cell types, FGF family members activate kinases of the ERK1/2 and p38 MAPK cascades in chondrocytes. Specific inhibitors of these pathways block FGF-2-induced and FGF-18-induced mitogenesis in chondrocytes and prevent FGF-2 induction of Sox9 in primary chondrocytes.^{253,258} The PI-3K pathway is required for the stimulation of proteoglycan synthesis by IGF-I in primary human articular chondrocytes, whereas the ERK1/2 pathway acts as a negative regulator.²⁸²

TGF- β and BMP family members transduce signals through the formation of heteromeric complexes of ligand-specific receptors, which have serine-threonine kinase

activity. The specificity of subsequent signals is determined mainly by the type I receptors. Type I and type II receptors are required for signal transduction (Figure 3-5).^{273,283,284} Seven types of type I receptors, called *activin receptor-like kinases* (ALKs), have been identified in mammals and have similar structures. TGF- β interacts with the type II receptor (T β RII), which recruits a TGF- β type I receptor (principally T β RI) to form a heterotrimeric receptor complex. The constitutively active T β RII kinase phosphorylates T β RI at serine and threonine residues. Three type I receptors, BMP type IA (BMPRI-IA or ALK-3), BMPRI-IB (ALK-6), and ALK-2, mediate BMP signaling. Although BMPRI receptors are able to bind ligand in the absence of type II BMP receptors, cooperativity has been shown in binding assays. On ligand binding, analogous to T β RI and T β RII, BMP type I receptors are phosphorylated by the

Figure 3-5 Bone morphogenetic protein (BMP) receptors and signaling cascade. BMPs are dimeric ligands with a single interchain, disulfide bond. BMPs interact with type I and II BMP receptors (BMPRI-I and BMPRI-II). BMPRI-II phosphorylates BMPRI-I and activates the serine/threonine kinase receptor. The BMPRI-I protein serine/threonine kinase phosphorylates cytoplasmic signaling substrates Smad 1 and Smad 5. This phosphorylation is modulated and inhibited by inhibitory Smad 6 and Smad 7. Phosphorylated Smad 1 and Smad 5 interact with a common co-Smad 4 and are translocated into the nucleus to initiate the transcription of BMP-response genes. A Smad-interacting protein (SIP) modulates binding of the Smad 1/Smad 4 complex to DNA. The bioavailability of BMP for interaction with cognate receptors depends on BMP binding proteins and antagonists, such as noggin and chordin, and extracellular matrix components, such as collagens and heparan sulfate. (From Reddi AH: Role of morphogenetic proteins in skeletal tissue engineering and regeneration, Nat Biotech 16:247–252, 1998.)

BMP type II receptors, which include activin (Act) RII, ActRIIB, and T-ALK. Spatial and temporal differences in the distribution of these receptors in different tissues can govern the response patterns to different members of the TGF- β /BMP family.

The canonical SMAD pathway mediates TGF- β and BMP signaling through phosphorylation of receptor-activated SMADs (R-SMADs). R-SMADs include Smad 1, Smad 5, and Smad 8 induced by BMPs and Smad 2 and Smad 3 induced by TGF- β . The SMADs are related to the *Drosophila* mothers against decapentaplegic (MAD) and nematode SMA signaling molecules. These regulatory SMADs form complexes with the common Smad 4 and translocate to the nucleus, where they bind to SMAD-specific DNA binding sites in the promoters of target genes.²⁸⁴ Other BMP-induced transcription factors include JunB, JunD, and inhibitor of DNA binding (ID) and distal-less homeo box (DLX) family members, suggesting alternative pathways of signaling. TGF- β and BMPs also can signal by activating TGF- β -activated kinase 1 (TAK1),²⁸⁵ which interacts with MEKK1 and activates p38 and JNK cascades, or by activating Ras/ERK1/2 or RhoA/ROCK signaling.^{273,284} Findings of numerous studies suggest that the differentiation of chondrocytes from mesenchymal precursors is positively regulated by p38 kinase and negatively regulated by ERK1/2.^{273,286} ERK1/2 activation cross-interacts with BMP-2-induced signaling to regulate chondrogenesis in a positive manner, whereas p38 activity is essential for the TGF- β induction of proteoglycan synthesis in articular chondrocytes.^{287,288} Cytoskeletal compartmentation of SMAD signaling complexes may regulate the differentiation of chondroprogenitor cells into chondrocytes.²⁷⁹

Inhibitory Smad 6 and Smad 7, which prevent phosphorylation of the R-SMADs, also control BMP-induced and TGF- β -induced activities. An additional SMAD-interacting molecule, Tob1, negatively regulates signaling by sequestering R-SMADs and is an antiproliferative protein that is downregulated in OA cartilage.²⁸⁹ BMP antagonists play important roles in spatial and temporal regulation of BMP activities during skeletal development. Originally discovered in *Xenopus*, they act as antagonists by determining the bioavailability of BMPs for binding to BMP receptors. The roles of noggin and chordin seem to be crucial for determining boundaries during joint morphogenesis. They display different spatial and temporal patterns of expression, binding affinities, and susceptibility to proteinases that release BMP. BMPs bind to chordin and noggin via cysteine-rich domains that are similar to domains in the N-terminal propeptides of fibrillar procollagens I, II, III, and V, which also bind BMPs and are susceptible to cleavage by MMPs.²⁸⁴ BMP may be released from chordin by cleavage with MMPs or BMP-1/tolloid, whereas noggin binds BMP with high affinity and cannot be cleaved to release BMP.

Follistatin, gremlin, chordin, and chordin-like 2 are upregulated in OA cartilage.²⁹⁰⁻²⁹² Follistatin, which has been linked to inflammatory processes; gremlin, which is associated with hypertrophic phenotype; and chordin appear at different stages of OA and with different topographic distribution. Because each antagonist binds preferentially to different BMPs, the differential expression may serve as a feedback mechanism to balance anabolic activities at different stages.

ROLE OF THE CHONDROCYTE IN CARTILAGE PATHOLOGY

The chondrocyte, the unique cell type in mature cartilage, maintains a stable equilibrium between the synthesis and the degradation of matrix components. During aging and joint diseases, such as RA and OA, this equilibrium is disrupted, and the rate of loss of collagens and proteoglycans from the matrix exceeds the rate of deposition of newly synthesized molecules. Cartilage destruction in OA is believed to be chondrocyte mediated in response to biomechanical insult, which may occur directly or indirectly through the production of cytokines and cartilage matrix-degrading proteinases in cartilage and other joint tissues (Figure 3-6).

Cartilage destruction in RA occurs primarily in areas contiguous with the proliferating synovial pannus as a result of the release and activation of proteinases from the synovial cells and, to some extent, at the cartilage surface exposed to matrix-degrading enzymes from polymorphonuclear neutrophils in the synovial fluids. In addition to the direct action of proteinases, RA synovial tissues contribute indirectly to cartilage loss by releasing cytokines and other mediators that act on the chondrocytes to produce dysregulation of chondrocyte function.²⁹³ Understanding of basic cellular mechanisms regulating chondrocyte responses to inflammatory cytokines has been inferred from numerous studies in vitro using cultures of cartilage fragments or isolated chondrocytes and is supported by studies in experimental models of inflammatory arthritis, such as collagen-induced arthritis and antigen-induced arthritis in mice.^{294,295}

Direct analysis of cartilage or chondrocytes from OA patients undergoing joint replacement has yielded more information than is available from RA patients, where cartilage damage is extensive. These studies indicate that chondrocytes produce not only proinflammatory cytokines, but also inhibitory and anabolic cytokines that modulate responses. The impact of cytokines on chondrocyte function, particularly with respect to their various roles in cartilage destruction, has been reviewed extensively.²⁻⁴ Studies of cartilage degradation in genetically modified mouse strains that are resistant to or accelerate the development of OA spontaneously with aging or when subjected to excessive biomechanical injury have yielded information about the molecular effectors of the disease and potential targets for therapy.^{296,297}

Cartilage Matrix-Degrading Proteinases

Chondrocytes synthesize and secrete MMPs in latent forms, which are activated outside the cells via activation cascades. An important cascade in cartilage is initiated by plasmin, the product of plasminogen activator activity, which may be produced by the chondrocyte; plasmin activates latent stromelysin (MMP-3), an activator of latent collagenases. In early studies, chondrocytes were among the first identified sources of TIMP-1, and they are now known to synthesize additional TIMPs. Chondrocytes are assumed to be a major source of the TIMPs and MMPs detected in synovial fluids, where they reflect an adaptive response to the local imbalance caused by increased production of

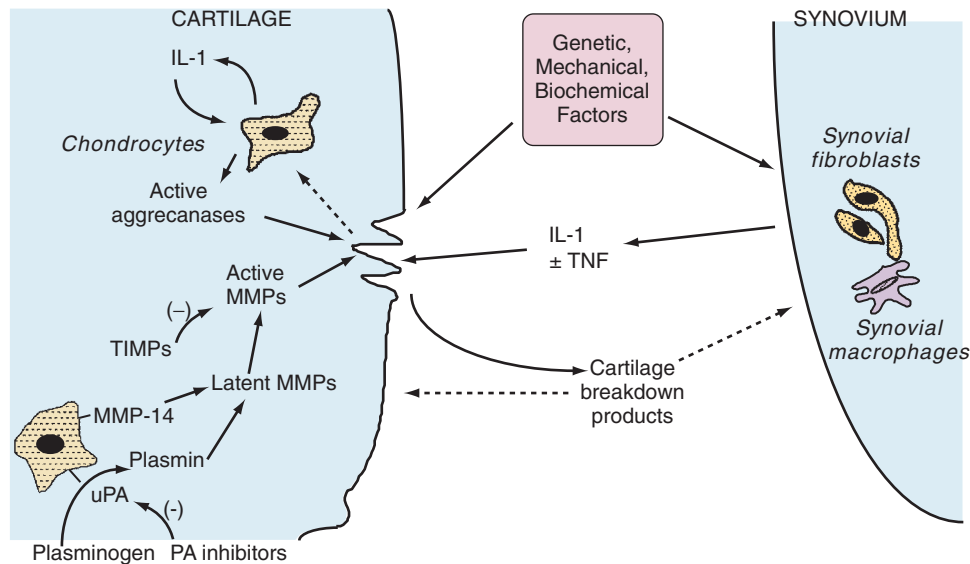

Figure 3-6 The role of chondrocyte-derived proteinases in cartilage destruction in osteoarthritis. Although studies in vitro and in vivo have shown that the chondrocyte can respond directly to mechanical loading, to catabolic cytokines such as interleukin-1 (IL-1) and tumor necrosis factor (TNF), and to cartilage breakdown products, the initiating signals and their relative importance have not been defined clearly. MMP, matrix metalloproteinase; TIMP, tissue inhibitor of metalloproteinase; uPA, urinary plasminogen activator. (From Goldring MB: *Osteoarthritis and cartilage: the role of cytokines*, Curr Rheumatol Rep 2:459–465, 2000.)

active MMPs by chondrocytes and other joint tissues. Collagenases 1, 2, and 3 (MMP-1, MMP-8, and MMP-13); gelatinases (MMP-2 and MMP-9); stromelysin-1 (MMP-3); membrane type 1 MMP (MT1)-MMP (MMP-14); and the aggrecanases, ADAMTS-4 and ADAMTS-5, specifically degrade native collagens and proteoglycans in cartilage matrix (Table 3-3).²⁹⁸⁻³⁰⁰

MMPs, aggrecanases, and the cleavage fragments generated by them are localized in regions of cartilage degradation^{111,301,302} and are detected in synovial fluids and cartilage from OA and RA patients.^{31,303} Expression of MMP-13 in OA and RA cartilage and its ability to degrade type II collagen more effectively suggest a major role for this enzyme in cartilage degradation. Postnatal overexpression of constitutively active MMP-13 in cartilage in mice produces OA-like changes in knee joints,³⁰⁴ and knockout of the gene encoding MMP-13 protects cartilage against surgically induced OA.³⁰⁵ Deficiency of DDR2, a collagen receptor whose activation is associated with upregulation of MMP-13, attenuates development of OA induced by DMM surgery.^{213,306} Deficiencies of the Runx2 and HIF2 α transcription factors that are key regulators of MMP-13 also protect against OA development or progression.^{105-107,307} Nuclear factor κ B (NF κ B) transcription factors in response to their upstream activating kinases can directly modulate the amplitude of MMP-13 expression under inflammation and other atypical stress-related states.³⁰⁸

Although elevated levels of MMPs in RA synovial fluids likely originate from the synovium, intrinsic chondrocyte-derived chondrolytic activity is present at the cartilage-pannus junction and in deeper zones of cartilage matrix in some RA specimens.^{309,310} MMP-1 is expressed at lower levels than MMP-3 and MMP-13 in the RA synovial pannus but is also produced by chondrocytes.³¹¹ MMP-10, similar to MMP-3, activates procollagenases and is produced by the synovium and chondrocytes in response to inflammatory

cytokines.³¹² MMP-14, produced principally by the synovial tissue, is important for synovial invasiveness, and antisense mRNA inhibition of this membrane proteinase has been shown to reduce cartilage destruction.³¹³

Several of the MMPs, including MMP-3, MMP-8, MMP-14, MMP-19, and MMP-20, are capable of degrading proteoglycans. Members of the reprotolysin-related proteinases of the ADAM family, particularly ADAMTS-4 and ADAMTS-5, are now regarded as the principal mediators of aggrecan degradation.^{299,300,314} The activities of MMPs and aggrecanases are complementary, however.³¹⁵ Of the aggrecanases, ADAMTS-5 is associated with increased susceptibility to OA, as shown in *Adamts5*-deficient mice.^{316,317} TIMP-3, but not TIMP-1, TIMP-2, or TIMP-4, is a potent inhibitor of ADAMTS-4 and ADAMTS-5 in vitro,^{318,319} and TIMP-3 deficiency results in mild cartilage degradation similar to that seen in patients with OA.³²⁰ A recent study indicates that syndecan-4 by controlling the synthesis of MMP-3 is a positive effector of ADAMTS-5 activation.²⁰⁷ Hedgehog signaling by modulating Runx2 may promote articular cartilage degradation via ADAMTS-5.³²¹

Cysteine proteinases, cathepsins B and L, and the aspartic proteinase, cathepsin D, are lysosomal enzymes that may play a secondary role in cartilage degradation via intracellular digestion of products released by other proteinases. Cathepsin B also may have a role in extracellular degradation of collagen telopeptides, collagens IX and XI, and aggrecan. Cathepsin K is expressed in synovial fibroblasts on the cartilage surface at the pannus-cartilage junction and is upregulated by inflammatory cytokines.³²² Among the known cathepsins, cathepsin K is the only proteinase that is capable of hydrolyzing type I and type II collagens at multiple sites within the triple-helical regions, and its requirement for acidic pH may be provided by the microenvironment between the synovial pannus and the cartilage.³²³

Table 3-3 Chondrocyte Proteinases That Mediate Degradation of Cartilage Matrix

Proteinase Class	Cartilage Matrix Substrates	Activity
Matrix Metalloproteinases		
Collagenases (MMP-1, MMP-8, MMP-13)	Collagens I, II	Fibrillar domain, 3/4 from N-terminus N-telopeptide (MMP-13)
Stromelysins (MMP-3, MMP-10)	Aggrecan core protein Aggrecan core protein Collagens IX, XI Link protein, fibronectin proMMPs, proTNF	Asn ³⁴¹ -Phe ³⁴² IGD Asn ³⁴¹ -Phe ³⁴² IGD Telopeptide region
Gelatinases (MMP-2, MMP-9)	Collagens II, XI Proteoglycans, link protein	Telopeptide or denatured collagen chains
Membrane-type MMPs MT-MMP-1 (MMP-14), MT-MMP-2, MT-MMP-3, MT-MMP-4 (MMP-15, MMP-16, MMP-17)	Collagen II Fibronectin, aggrecan ProMMP-2 ProMMP-13 ProTNF	Telopeptide
Matrilysin (MMP-7) Enamelysin (MMP-20)	Link protein COMP, link protein	
Aggrecanases		
ADAMTS-1, ADAMTS-4, ADAMTS-5	Aggrecan core protein IGD	Glu ³⁷³ -Ala ³⁷⁴ , Glu ¹⁵⁴⁵ -Gly ¹⁵⁴⁶ , Glu ¹⁷¹⁴ -Gly ¹⁷¹⁵ , Glu ¹⁸¹⁹ -Ala ¹⁸²⁰ , Glu ¹⁹¹⁹ -Leu ¹⁹²⁰
Serine		
Plasminogen activators (tPA, uPA) Cathepsin G High temperature requirement A1 (HTRA1)	Aggrecan, fibronectin, proMMPs Aggrecan, collagen II, proMMPs Matrilin 3, fibronectin, biglycan, fibromodulin, COMP, collagen VI	Activation of plasminogen gives rise to plasmin Degrades pericellular matrix
Cysteine		
Cathepsins B, K, L, S	Collagens IX, XI Link protein, aggrecan	Telopeptides (optimal pH 4.0-6.5)
Aspartate		
Cathepsin D	Phagocytosed ECM components	In lysosomes (optimal pH 3.0-6.0)

ADAMTS, a disintegrin and metalloproteinase with thrombospondin-1 domains; COMP, cartilage oligomeric matrix protein; ECM, extracellular matrix; IGD, interglobular domain; MMP, matrix metalloproteinase; MT-MMP, membrane-type MMP; proMMP, proenzyme form of MMP; TNF, tumor necrosis factor; tPA, tissue-type plasminogen activator; uPA, urokinase-type plasminogen activator.

MT1-MMP (MMP-14) also may serve as an activator of other MMPs produced by chondrocytes. Other MMPs, including MMP-16 and MMP-28,^{324,325} and numerous ADAM/ADAMTS family members, including ADAM-17/TACE (TNF converting enzyme),³²⁶ are expressed by chondrocytes, but their roles in cartilage have yet to be defined.^{298,327} Identification of the precise roles of these proteinases and their endogenous inhibitors in chondrocyte-mediated cartilage degradation has provided the opportunity to develop targeted therapies that interfere with the activities of aggrecanases or MMPs without disrupting normal physiology.^{299,300,328} In that regard, microRNAs are novel endogenous regulators in cartilage.³²⁹ MicroRNA-140 downregulates ADAMTS-5 expression in normal cartilage, and its expression is reduced in OA cartilage and is suppressed by exposing chondrocytes to IL-1 β .³³⁰ MicroRNA-140 knockout mice are predisposed to age-related OA development, and overexpression of microRNA-140 in chondrocytes is protective against surgically induced OA.³³¹

Balance of Cytokines in Cartilage Destruction

Of the cytokines that affect cartilage metabolism, most are pleiotropic factors that were identified originally as immunomodulators but were found to regulate cellular functions

in cells of mesenchymal origin. IL-1 and TNF not only stimulate chondrocytes to synthesize cartilage matrix-degrading proteinases, they also regulate matrix protein synthesis and cell proliferation. Considerable redundancy and overlap in biologic activities exist among the individual cytokines, and they do not act alone, but rather in synergy or partnership with or in opposition to other cytokines via cytokine networks. In addition to IL-1 and TNF, other catabolic cytokines have been characterized, as have inhibitory or anabolic cytokines produced by the chondrocytes themselves or by other cells in joint tissues (Table 3-4). Investigations in vitro and in vivo have begun to sort out the complexities of the cytokine networks and to determine how the balance in normal homeostasis can be restored when it is disrupted (Figure 3-7). Studies of type II collagen-induced arthritis and other types of induced arthritis in transgenic animals with overexpressed or deleted genes encoding cytokines, their receptors, or activators have provided further insight into the roles of these factors in cartilage destruction.

Interleukin-1 and Tumor Necrosis Factor

IL-1 and TNF are the predominant catabolic cytokines involved in the destruction of articular cartilage. The first

Figure 3-7 The cytokine balance in cartilage metabolism. Soluble mediators toward the left of the balance promote the loss of cartilage matrix. Mediators on the right side prevent the synthesis or actions of catabolic cytokines and prevent loss of cartilage matrix. Anabolic factors, including insulin-like growth factor I (IGF-I) and bone morphogenetic proteins (BMPs), and prostaglandin E₂ (PGE₂) maintain or promote cartilage matrix synthesis. IL-1, interleukin-1; IL-1Ra, IL-1 receptor antagonist; LIF, lymphocyte-activating factor; OSM, oncostatin M; sTNF-R, soluble TNF receptor; TNF, tumor necrosis factor. (Adapted from Goldring MB: *Osteoarthritis and cartilage: the role of cytokines*, Curr Rheumatol Rep 2:459–465, 2000.)

recognition of IL-1 as a regulator of chondrocyte function stems largely from the early work of Fell and others,^{332,333} who identified a soluble factor, termed *catabolin*, in supernatants of normal, noninflamed porcine synovial fragment cultures that stimulated chondrocytes to degrade the surrounding cartilage matrix. Similar activities in culture supernatants from mononuclear cells and rheumatoid synovium were attributed to IL-1,^{334,335} and the catabolin isoforms were identified as IL-1 α and IL-1 β .³³⁶ Since those early findings, numerous studies in vitro and in vivo indicate that IL-1 and TNF, originating primarily from the inflamed synovium, are the predominant catabolic cytokines involved in the destruction of articular cartilage in RA.²⁹³⁻²⁹⁵

Major events in OA pathogenesis occur within the cartilage itself, and evidence suggests that chondrocytes participate in this destructive process not only by responding to cytokines released from other joint tissues but also by synthesizing them.^{337,338} They may be exposed continuously to the autocrine and paracrine effects of IL-1 and other inflammatory mediators at high local concentrations. Chondrocytes in OA cartilage, especially those in clonal clusters, are positive for IL-1 immunostaining and express IL-1 β converting enzyme (caspase-1) and type 1 IL-1 receptor (IL-1R1).³³⁹ IL-1 co-localizes with TNF, MMP-1, MMP-3, MMP-8, MMP-13, and type II collagen cleavage epitopes

in regions of matrix depletion in OA cartilage.^{111,301,340} The increased sensitivity of OA chondrocytes to IL-1 and TNF may be associated with increased levels of IL-1R1 and p55 TNF receptor at localized sites.^{341,342} Co-localization of these cytokines, MMPs, and type II collagen cleavage epitopes has been reported in regions of matrix depletion in RA cartilage.^{133,343}

Originally known as *cachectin*, TNF produces many effects on chondrocytes in vitro that are similar to those of IL-1 β , including stimulation of the production of matrix-degrading proteinases and suppression of cartilage matrix synthesis.^{337,338} Although IL-1 β is 100-fold to 1000-fold more potent on a molar basis than TNF, strong synergistic effects occur at low concentrations of the two cytokines together, eliciting more severe cartilage damage than injection of either cytokine alone.²⁹⁴ The concept that TNF drives acute inflammation, whereas IL-1 β has a pivotal role in sustaining inflammation and cartilage erosion, has been derived from work in animal models of RA using cytokine-specific neutralizing antibodies, soluble receptors, or receptor antagonists and in transgenic or knockout mouse models.^{294,295} In a surgically induced OA model, IL-1 β knockout mice are protected against cartilage damage.²⁹⁶ A more recent study showed that crossing arthritic human TNF transgenic (hTNFtg) mice with mice deficient in both IL-1 α and IL-1 β protects against cartilage erosion without affecting synovial inflammation.³⁴⁴

Table 3-4 Cytokines That Regulate Cartilage Destruction

Catabolic	IL-1 Tumor necrosis factor IL-17 IL-18
Modulatory	IL-6 Leukemia inhibitory factor Oncostatin M IL-11
Inhibitory	IL-4 IL-10 IL-13 IL-1 receptor antagonist

IL, interleukin.

Cytokine Networks

IL-1 β and TNF can induce chondrocytes to produce several other proinflammatory cytokines, including IL-6, leukemia inhibitory factor, IL-17, IL-18, and chemokines.^{337,338,345} IL-6 seems to play a dual role by increasing expression of IL-1 receptor antagonist (IL-1Ra), soluble TNF receptor, and TIMPs, while also enhancing immune cell function and inflammation.^{325,346} The activity of IL-6 requires soluble IL-6 receptor to synergize with IL-1 to stimulate expression of MMPs and ADAMTS and to downregulate COL2A1 and aggrecan in cultured chondrocytes.^{347,348} IL-6 knockout mice are more susceptible to cartilage degeneration during

aging,³⁴⁹ however, suggesting that this cytokine may play a protective role in normal physiology.

Other members of the IL-6 family that act via receptors that heterodimerize with gp130 also may serve modulatory roles. IL-11 shares several actions of IL-6, including stimulation of TIMP production, without affecting MMP production by chondrocytes,³⁴⁷ and it may inhibit cartilage destruction.³⁵⁰ Leukemia inhibitory factor (LIF) participates in a positive feedback loop by increasing the production of IL-6 by chondrocytes. Oncostatin M (OSM), a product of macrophages and activated T cells, is a potent stimulator of chondrocyte production of MMPs and aggrecanases in synergism with IL-1 β or TNF.^{312,347,351} Direct evidence supporting a role for OSM in contributing to cartilage loss in inflammatory arthritis is provided by studies in animal models.^{352,353}

IL-17 and IL-18 are potent catabolic factors that stimulate the production of IL-1 β , MMPs, IL-6, inducible nitric oxide synthase (iNOS), cyclooxygenase (COX)-2, and microsomal PGE synthase-1 (mPGES-1) by human chondrocytes.³⁵⁴ IL-17 is produced by activated T helper type 1 (Th1), or CD4⁺, lymphocytes and binds to a receptor that is not related to any known cytokine receptor family. IL-17A, one of at least six family members, is primarily a product of Th17 cells, a newly described subset of T cells, and is a potent inducer of catabolic responses in chondrocytes by itself or in synergy with other cytokines.³⁵⁵ IL-17 can drive T cell-dependent erosive arthritis in TNF-deficient and IL-1Ra knockout mice, and treatment of collagen-induced arthritis or antigen-induced arthritis mice with neutralizing IL-17 antibody effectively inhibits cartilage destruction in those models of RA.³⁵⁶ A role for IL-17 in the promotion of angiogenesis through induction of VEGF in OA chondrocytes and synovial fibroblasts has been proposed.³⁵⁷

IL-18 is produced by macrophages, its receptor shares homology with IL-1RI, and it has effects similar to IL-1 β in human chondrocytes, but it stimulates chondrocyte apoptosis.^{358,359} IL-18 deficiency or blockade with IL-18-neutralizing antibody or IL-18-binding protein reduces cartilage destruction and inflammation, and IL-18 gene transfer promotes IL-1 β -driven cartilage destruction in a TNF-independent manner.³⁶⁰ Of the other members of the IL-1 family identified by DNA database searches, IL-1F8 seems to be capable of stimulating IL-6, IL-8, and nitric oxide production by human chondrocytes, but at 100-fold to 1000-fold higher concentrations than IL-1 β .³⁶¹ IL-32, a more recently discovered cytokine that induces TNF, IL-1 β , IL-6, and chemokines and is expressed in the synovia of patients with RA, contributes to TNF-dependent inflammation and cartilage proteoglycan loss.³⁶²

Inhibitory Cytokines

IL-4, IL-10, IL-13, and the naturally occurring IL-1Ra are classified as inhibitory cytokines because they decrease the production and activities of catabolic and proinflammatory cytokines in chondrocytes *in vitro* and suppress cartilage destruction *in vivo* (see Table 3-4).^{294,339,363,364} IL-4 and IL-10 inhibit cartilage-degrading proteinases and reverse some effects of catabolic cytokines *in vitro*; together they produce synergistic suppression of cartilage destruction *in vivo*.

The efficacy of IL-4, IL-10, and IL-13 in retarding cartilage damage may be related in part to their stimulatory effects on IL-1Ra production,^{339,365} and their therapeutic application has been proposed as a means of restoring the cytokine balance in RA.³⁶⁶ IL-1Ra is capable of blocking the actions of IL-1 if added at sufficiently high concentrations *in vitro* and is among the first agents to be developed for anticytokine therapy.^{293,367} IL-1Ra can be produced by the same cells that secrete IL-1 and exists as at least three isoforms, including an intracellular form.

Despite the capacity of IL-4 to inhibit the effects of proinflammatory cytokines on chondrocyte function,^{368,369} differential effects have been observed in mice depending on the model.^{370,371} Gene transfer of IL-10 in combination with IL-1Ra inhibits cartilage destruction through a mechanism involving activin, a TGF- β family member.³⁷² IL-10 is part of the response induced by immunomodulatory neuropeptides that have been shown to inhibit inflammation and cartilage and bone destruction by downregulating the Th1-driven immune response and upregulating IL-10/TGF- β -producing T regulatory lymphocytes.³⁷³ IL-13 decreases the breakdown of collagen and proteoglycans by inhibiting MMP-3 and MMP-13 expression induced by a combination of IL-1 α and OSM and by upregulating TIMP-1, but it increases MMP-1.³⁷⁴ Local gene transfer of IL-13 inhibits chondrocyte death and MMP-mediated cartilage degradation despite enhanced inflammation in the immune complex arthritis model.³⁷⁵ The inhibitory cytokines may have direct effects on cartilage metabolism and indirect effects by mediating the production and actions of catabolic cytokines.

Other Mediators

The balance of mediators determining normal homeostasis is complex, and modulation of their activities may produce positive or negative effects on chondrocyte function. In addition to inducing the synthesis of MMPs and other proteinases by chondrocytes, IL-1 β and TNF upregulate the production of nitric oxide via iNOS (or NOS2) and prostaglandin E₂ (PGE₂) by stimulating the expression or activities of COX-2, mPGES-1, and soluble phospholipase A₂. In the production of prostaglandins, mPGES-1, which is induced by IL-1 β in chondrocytes, is a major player.^{376,377} Although PGE₂ and nitric oxide have been well characterized as proinflammatory mediators, evidence suggests that they also may be protective and may play roles in chondrocyte survival and responses to mechanical stress. COX-2 is involved in the chondrocyte response to high shear stress, which is associated with reduced antioxidant capacity and increased apoptosis.³⁷⁸ The mechanisms of cross-talk between prostaglandins and nitric oxide in chondrocytes have been reviewed.³⁷⁷

Another regulator is peroxisome proliferator-activated receptor γ (PPAR γ), which is activated by the endogenous ligand 15-deoxy- $\Delta^{12,14}$ prostaglandin J₂ (PGJ₂). PPAR γ activation opposes the induction of COX-2, iNOS, MMPs, and mPGES-1 and the suppression of aggrecan synthesis by IL-1.^{354,379} PPAR α agonists may also protect chondrocytes against IL-1-induced responses by increasing the expression of IL-1Ra.³⁸⁰ The IL-1 β -induced COX-2 response depends on the differentiated phenotype of chondrocytes, and PGE₂

opposes the effects of IL-1 β by stimulating type II collagen and inhibiting type I collagen gene expression.^{381,382}

Roles for nitric oxide as a mediator of other IL-1–induced responses, including inhibition of aggrecan synthesis, enhancement of MMP activity, and reduction of IL-1Ra synthesis, also have been suggested.³⁸³ Nitric oxide may increase chondrocyte susceptibility to injury by other oxidants and thus may contribute to resistance to anabolic effects of IGF-I. Nitric oxide has been implicated as an important mediator in chondrocyte apoptosis. PGE₂ may mediate directly the induction of apoptosis by nitric oxide or may sensitize chondrocytes to nitric oxide–induced apoptosis.³⁸⁴ However, evidence indicates that nitric oxide may inhibit cytokine production or activity in chondrocytes. IL-1 seems to protect chondrocytes from CD95–induced apoptosis through a mechanism that is independent of IL-1–induced nitric oxide.

Novel mediators that affect chondrocyte metabolism include the IL-1–induced suppressor of cytokine signaling 3 (SOCS3), which acts as a negative feedback regulator during IGF-I desensitization in the absence of nitric oxide by inhibiting insulin receptor substrate-1 phosphorylation.²⁴⁷ The receptor for advanced glycation end products (RAGE) interacts preferentially with S100A4, a member of the S-100 family of calcium-binding proteins, in chondrocytes and stimulates MMP-13 production.³⁸⁵ Recent studies indicate that S100A8, S100A9, and S100A11 have critical roles in inflammatory arthritis and OA.^{386–388} The fibroblast activation protein α , a membrane serine proteinase, which co-localizes in synovium with MMP-1 and MMP-13 and is induced by IL-1 β and OSM in chondrocytes, may play a role in collagen degradation.^{389,390} Many of these proteins may be activated during the chondrocyte response to abnormal stimuli, thereby serving as endogenous mediators of cellular responses to stress and inflammation.

Adipokines, which were identified originally as products of adipocytes, also have roles in cartilage metabolism.³⁹¹ White adipose tissue is a major source of proinflammatory and anti-inflammatory cytokines, including IL-1Ra and IL-10,³⁹² and the dysregulated balance between leptin and other adipokines, such as adiponectin, promotes destructive processes during inflammation.³⁹³ Leptin expression is enhanced during acute inflammation, correlating negatively with inflammatory markers in RA sera,³⁹⁴ and may serve as a link between the neuroendocrine and immune systems.³⁹⁵ Elevated expression of leptin in OA cartilage and in osteophytes and its capacity to stimulate IGF-I and TGF- β 1 synthesis suggest a role for this adipokine in anabolic responses of chondrocytes.³⁹⁶ Leptin synergizes with IL-1 or interferon- γ to increase nitric oxide production in chondrocytes,³⁹⁷ and leptin deficiency attenuates inflammatory processes in experimental arthritis.³⁹⁸

Human articular chondrocytes are capable of expressing receptors of the IL-1R/Toll-like receptor (TLR) superfamily, including TLR1, TLR2, and TLR4. IL-1 and TNF induce the expression of TLRs in chondrocytes and peptidoglycans, and lipopolysaccharide and fibronectin fragments act as TLR ligands. TLR activation is associated with increased production of MMPs, nitric oxide, PGE, and VEGF.^{399,401} Cartilage proteoglycan loss in streptococcal cell wall–induced arthritis is predominantly dependent on TLR2 signaling.⁴⁰² In immune complex–mediated arthritis, TLR4

regulates cartilage destruction by IL-10–mediated upregulation of Fc γ receptor expression and enhanced cytokine production.⁴⁰³ A recent study showed that two endogenous shared TLR-2/TLR-4 ligands—low-molecular-weight hyaluronan (LMW-HA) and high-mobility group box chromosomal protein 1 (HMGB-1)—which are increased in OA joints, promote MMP-13–mediated ECM remodeling and chondrocyte differentiation toward hypertrophy by engaging TLR-dependent, MyD88 (myeloid differentiation factor 88) signaling, leading to the activation of NF κ B–dependent genes, including MMP-13.⁴⁰⁴

Chemokines

Chemokines, which are small heparin-binding cytokines identified originally as chemotactic factors, are classified as C, CX3C, or CC molecules, indicating the presence of distinct N-terminal cysteine (C) residues. Chondrocytes, when activated by IL-1 and TNF, express several chemokines, including IL-8, monocyte chemoattractant protein (MCP)-1, MCP-4, macrophage inhibitory protein (MIP)-1 α , MIP-1 β , RANTES (regulated on activation normal T cell expressed and secreted), and growth-related oncogene (GRO) α , and the receptors that enable responses to some of these chemokines and may feedback-regulate synovial cell responses (Table 3-5).^{405–407} The first report of expression of functional CC and CXC chemokine receptors (CCR and CXCR) on chondrocytes showed that interaction of these receptors with their corresponding ligands—MCP-1, RANTES, and GRO α —resulted in upregulation of MMP-3.⁴⁰⁵

Normal and OA chondrocytes express the CC chemokines, MCP-1, MIP-1 α , MIP-1 β , and RANTES. RANTES increases expression of its own receptor, CCR5. MCP-1 and RANTES increase MMP-3 expression, inhibit proteoglycan synthesis, and enhance proteoglycan release from the chondrocytes. The RANTES receptors CCR3 and CCR5, but not CCR1, are expressed in normal cartilage, whereas all three receptors are expressed in OA cartilage or after stimulation of normal chondrocytes by IL-1 β . RANTES induces the expression of iNOS, IL-6, and MMP-1.

Table 3-5 Chemokines and Receptors in Chondrocytes*

Functional Name	Systematic Name	Chemokine Receptor
GRO α	CXCL1	CXCR1, CXCR2
IL-8	CXCL8	CXCR1, CXCR2
MCP-1	CCL2	CCR2
MIP-1 α	CCL3	CCR1, CCR5
MIP-1 β	CCL4	CCR5
RANTES	CCL5	CCR1, CCR3, CCR5
SDF-1	CXCL12	CXCR4

*Chemokines are classified according to the positions of the first two cysteines (C) of the four conserved N-terminal cysteines: CC chemokine ligand (CCL), first two cysteines are adjacent; CXC chemokine ligand (CXCL), first two cysteines are separated by amino acid X other than cysteine; CCR, CC chemokine receptor; CXCR, CXC chemokine receptor.

GRO α , growth-related oncogene α ; IL-8, interleukin-8; MCP-1, monocyte chemoattractant protein-1; MIP-1, macrophage inhibitory protein-1; RANTES, regulated on activation, normal T cell expressed and secreted; SDF-1, stromal-derived growth factor-1.

High levels of stromal cell–derived factor 1 (SDF-1) are detected in RA synovial fluids, and its receptor, CXCR4, is expressed by chondrocytes, but not by synovial fibroblasts, suggesting a direct influence of this chemokine on cartilage damage.⁴⁰⁸ Microarray studies have elucidated many chemokines that are inducible in chondrocytes by fibronectin fragments and cytokines.^{189,409} SDF-1 and several other chemokines also increase the synthesis of S100A, N-acetyl- β -D-glucuronidase, cathepsin B, and MMPs by chondrocytes and DNA synthesis, cell proliferation, and PGE₂ production.^{410,411} OA chondrocytes in contact with autologous T lymphocytes produce enhanced levels of MMP-1, MMP-3, MMP-13, and RANTES.⁴¹² In addition to recruiting leukocytes to sites of inflammation in arthritic joints and mediating synovial fibroblast responses and actions, chemokines are capable of modulating chondrocyte functions that are associated with cartilage degradation.

Cytokine Signaling Pathways Involved in Cartilage Metabolism

Although the receptors for IL-1 and TNF and associated adapter molecules are distinct, they share the capacity to activate some of the same signaling pathways (Figure 3-8).^{337,363,413,414} The major pathways induced by catabolic cytokines involve signal transduction by the stress-activated

protein kinases, JNKs and p38 kinases, and the NF κ B and PI-3K pathways. The JAK/STAT signaling pathway is important for signaling by gp130 cytokines, including IL-6 and OSM.⁴¹⁵ Specific adapter molecules involved in the pathways induced by TNF receptors, which are members of the TNF receptor superfamily, are different from the adapter molecules used by IL-1 signaling pathways. The TNF receptor pathway uses TNF receptor–associated factor 2 (TRAF2), TRAF6, and the receptor interacting protein kinase, whereas the IL-1 receptor pathway uses TRAF6, IL-1 receptor–associated kinase (IRAK), and evolutionarily conserved signaling intermediate in Toll pathways (ECSIT) as adapter molecules. Signaling through TNF-RI associated with TNF receptor–associated death domain (TRADD) activates apoptosis, whereas TNF-RII signaling through TRAF2 activates JNK and NF κ B.

In contrast to ERK1 and ERK2, p38 and JNK signaling pathways are weakly activated by growth factors. Studies in chondrocytes in vitro have shown that the p38 and JNK cascades mediate the induction of proteinases and proinflammatory genes by IL-1 and TNF.³⁶³ These pathways also may be activated in chondrocytes by mechanical stress and cartilage matrix products via integrins and other receptor-mediated events.⁴¹⁶⁻⁴¹⁸ Upregulation of IL-1 and TNF expression via mechanotransduction pathways suggests their involvement as secondary mediators in a feedback

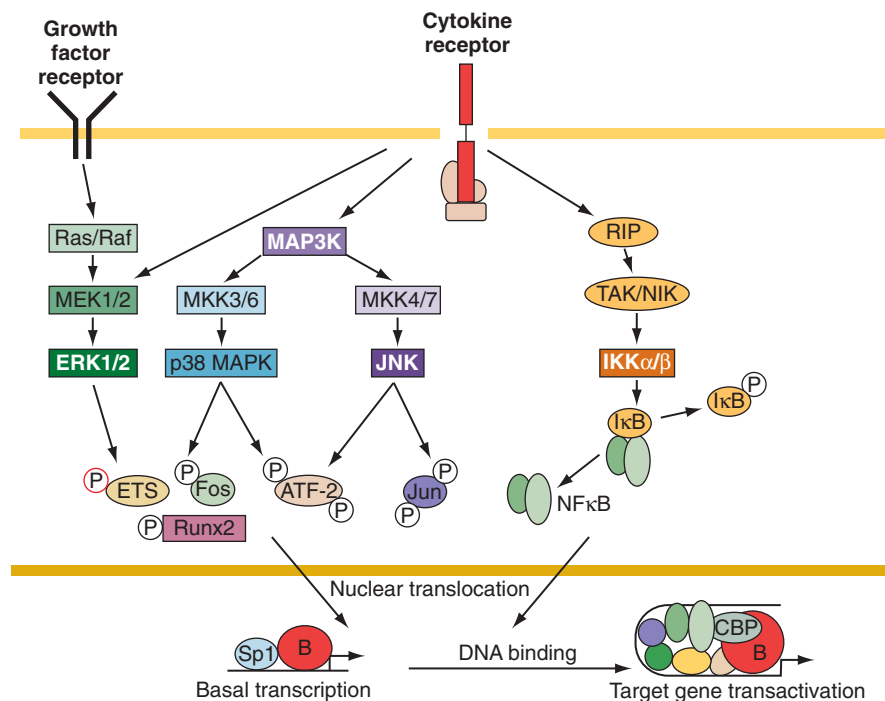

Figure 3-8 Intracellular signaling pathways activated by interleukin-1 (IL-1) in chondrocytes. Binding of IL-1 to the type I IL-1 receptor (IL-1R1) leads to recruitment of the IL-1R accessory protein (IL-1RAcP). Cytoplasmic Toll/IL-1 receptor (TIR) domains of the receptor recruit MyD88 via its TIR, and the MyD88 death domain (DD) recruits IL-1 receptor–associated kinases (IRAK and IRAK2) to the receptor complex before being rapidly phosphorylated and degraded. The IRAKs mediate tumor necrosis factor receptor–associated factor 6 (TRAF6) oligomerization, initiating various protein kinase cascades, the major ones of which involve (1) the stress-activated protein kinases, p38 mitogen-activated protein kinase (MAPK), and c-Jun N-terminal kinase (JNK), which lead to activation of activator protein-1 (AP-1) (c-Fos/c-Jun), activating transcription factor-2 (ATF-2) and E26 transformation-specific (ETS) factors, among other transcription factors; and (2) inhibitor of κ B (I κ B) kinases α and β (IKK- α and IKK- β), which lead to activation of nuclear factor κ B (NF κ B). TNF also stimulates these pathways, but mainly via TRAF2. Other signaling pathways may influence the target gene responses, such as growth factor–induced or chemokine–induced phosphatidylinositol 3-kinase (PI-3K) via the serine/threonine kinase, Akt/protein kinase B, and gp130 cytokine–induced janus activating kinase (JAK)/signal transducer and activator of transcription (STAT) pathway. Responses of the target genes depend on the presence of DNA sequences within the respective promoters that bind to various transcription factors.

mechanism. At least four isoforms of p38 MAPK exist with different substrate specificities and differential effects on essential chondrocyte functions.

JNKs are serine threonine protein kinases that phosphorylate Jun family members, components of AP-1 transcription factors, and they exist in humans as three JNK isoforms: JNK1, JNK2, and JNK3. A potent JNK1/2 inhibitor, SP600125, which blocks inflammation and joint damage in animal models of RA, and other JNK isoform-specific inhibitors are useful tools for analyzing chondrocyte function *in vitro* and *in vivo*. Activated JNK is detected in OA, but not in normal cartilage, and JNK inhibition attenuates cytokine-induced chondrocyte responses.^{419,420}

NFκBs are released from inhibitory IκBs by the catalytic activities of the IKKα and IKKβ subunits of the IKK signalosome complex, permitting translocation of active NFκB to the nucleus.^{308,421} In response to a host of proinflammatory stimuli, IKKβ is the dominant IκBα kinase *in vivo*, whose activation is essential for the nuclear entry of canonical NFκB heterodimers^{308,421}; thus ablation of IKKβ in adult chondrocytes could protect them from the stress and inflammatory responses of OA disease onset or progression. The latter would also be in keeping with the beneficial anti-inflammatory effects of physiologic biomechanical signals, which have been reported to inhibit IKK-mediated NFκB activation in chondrocytes.⁴²²

NFκB mediates the expression of cytokines and chemokines induced by fibronectin fragments,¹⁸⁹ and inhibition of DNA-binding activity of NFκB by agents that deplete polyamine blocks IL-1 and TNF without promoting chondrocyte apoptosis.⁴²³ Chondrocyte phenotype appears to be subject to differential control by IKKα-driven noncanonical and IKKβ-driven canonical NFκB.¹⁴⁸ In addition to NFκB, transcription factors that are members of the C/EBP, ETS, and AP-1 families are important for the regulation of gene expression by IL-1 and TNF in chondrocytes.⁷⁵ Activation of protein kinase C ζ (PKCζ) appears to be necessary upstream of NFκB in OA articular chondrocytes.⁴²⁴ It is interesting to note that PKCζ-mediated NFκB RelA/p65 Ser311 phosphorylation has been shown to maintain RelA/p65 activity through a novel mechanism involving suppression of SETD6-mediated lysine 310 methylation.⁴²⁵

ROLE OF THE CHONDROCYTE IN CARTILAGE REPAIR

Aging of Articular Cartilage

It is important, but often difficult, to distinguish among the effects of aging itself and diseases such as OA that become more common with increasing age.^{227,426} In both cases, biochemical alterations in matrix composition are reflected in changes in cartilage structure.⁴²⁷ The thickness of articular cartilage, as shown by magnetic resonance imaging, decreases with increasing age.⁴²⁸ Heterogeneous depletion of glycosaminoglycans at the cartilage surface and fatigue fracture of superficial collagen bundles may contribute to the mild splitting and fraying of superficial cartilage, which is termed *fibrillation*. If fibrillation progresses into deeper layers of cartilage, abnormal multicellular clusters of chondrocytes that stain intensely for glycosaminoglycans are

found at the base of clefts. These changes include decreased size and aggregation of aggrecan and increased collagen denaturation, resulting in loss of compressive stiffness and tensile strength.⁸

Zonal differences in tensile strength and compressive resistance are related to differences in matrix composition and can be observed to change during the aging of adult articular cartilage and in response to traumatic damage. The territorial, or pericellular, matrix and the interterritorial matrix differ in the amounts and types of matrix proteins. The chondrocytes are normally surrounded by a 2 μm pericellular matrix, composed of a highly branched filamentous network of collagen VI tetramers, which serves as a scaffold for decorin, biglycan, perlecan, and chondroadherin, which predominate in this region, and hyaluronan, fibrillin-1, and PRELP. The interterritorial region, in contrast, contains primarily a collagen II/XI fibril network, which binds decorin, fibromodulin, collagen IX, and COMP, and large numbers of intact aggrecan molecules attached via link protein to long chains of hyaluronic acid. In the deep zone, the interterritorial region most remote from the cells contains a larger number of degraded aggrecan molecules that lack the G3 domain.

Proteoglycans in aged cartilage have a wide range of sizes, with small forms resulting from low substitution of glycosaminoglycan residues and shorter lengths compared with glycosaminoglycans in young articular cartilage.⁸ Unsubstituted proteoglycan core proteins of aggrecan and biglycan are detectable in articular cartilage from elderly subjects. Hyaluronan content increases in aged cartilage, but with reduced mean chain length, and link protein seems to be fragmented. Collagen fibrils become thinner with age and are less densely packed. Nonenzymatic glycation results in the formation and accumulation of the advanced glycation end product pentosidine in long-lived proteins, including cartilage collagen and aggrecan.⁴²⁹ Such biochemical changes may result in part from changes in chondrocyte synthetic function and from increased susceptibility of the matrix to degradation.⁴³⁰ Increased and more extensive collagen degradation can be observed in cartilage from older, healthy individuals, and, similar to cartilage in early OA, the damage is concentrated closer to the articular surface and co-localizes with MMP-13 activity.¹¹¹ (See Chapter 98 for a detailed discussion of the pathogenesis of OA.)

Aging Chondrocyte

Chondrocyte function, including mitotic and synthetic activity, deteriorates with age. Degradative changes are generally due to the actions of proteinases and are, at least in part, the cumulative consequences of adverse conditions, such as mechanical insults or inflammation, to which the chondrocyte is exposed throughout life. Deficiencies in cartilage matrix proteins also may disrupt chondrocyte-matrix interactions that are important to cell survival. The decline in chondrocyte number may be attributed to increased cell death with age. Although programmed cell death, or apoptosis, increases with age in adult rats and mice, this may be due to skeletal growth that occurs throughout life in these animals. In human adult cartilage, apoptotic cell removal does not seem to be common, however.³⁹ Replicative senescence, detected as β-galactosidase activity and decreased

telomere length, has been proposed to contribute to age-related changes in the proliferative potential of adult articular chondrocytes.^{431,432}

TGF- β , FGFs, IGF-I, and other anabolic factors that support cartilage matrix biosynthesis are expressed at declining levels with aging, or their activities are downregulated.²²⁷ The capacity of BMP-6 to stimulate proteoglycan synthesis and the production of BMP-7 (OP-1) decline with age.^{230,277} Chondrocytes also show an age-related decline in the anabolic response to IGF-I, possibly owing to increased synthesis of IGFBP-3, which is itself antiproliferative. Chondrocytes from elderly donors depend strongly on IGF-I and IGF-II for survival.²³³ It has been proposed that the reduction in TGF- β signaling in aging chondrocytes may be a factor in their reduced capacity to repair cartilage.⁴³³

Markers of Cartilage Matrix Degradation and Turnover

With increasing knowledge of the composition of the cartilage matrix, molecular markers in body fluids have been identified for monitoring changes in cartilage metabolism and for assessing joint damage in arthritis.^{32,33,434} Molecules originating from the articular cartilage, including aggrecan fragments containing chondroitin sulfate and keratan sulfate; type II collagen fragments; collagen pyridinoline cross-links; and COMP, usually are released as degradation products as a result of catabolic processes. Specific monoclonal antibodies have been developed for analyzing OA and RA body fluids for products of proteoglycan or collagen degradation (catabolic epitopes) or synthesis of newly synthesized matrix components (anabolic neoepitopes), which represent attempts to repair the damaged matrix. Different monoclonal antibodies can distinguish subtle biochemical differences in chondroitin sulfate or keratan sulfate chains that result from degraded versus newly synthesized proteoglycans. Such epitopes can be detected in the synovial fluids and sera of patients with OA and RA, and the synovial fluid-to-serum ratio has been suggested as a potential diagnostic indicator. The degradation of aggrecan in cartilage has been characterized using antibodies 846, 3B3(-), and 7D4, which detect chondroitin sulfate neoepitopes; 5D4, which detects keratan sulfate epitopes; and the VIDIPEN and NITEGE antibodies, which recognize aggrecanase and MMP cleavage sites within the interglobular G1 domain of aggrecan (see Chapter 8).^{299,300}

Similarly, the synthesis of type II collagen can be monitored by measuring serum and synovial fluid levels of the carboxyl-terminal propeptide, and urinary excretion of hydroxyllysyl pyridinoline cross-links may indicate collagen degradation.^{32,33} Specific antibodies that recognize epitopes on denatured type II collagen at the collagenase cleavage site are promising diagnostic reagents. These include the C12C antibody (previously known as *Col2-3/4C Long mono*) that has been used to detect cleavage of the triple helix of type II collagen in experimental models and in OA and RA cartilage.^{111,343} The ratios of these markers to the synthetic marker, CPII, are associated with a greater likelihood of radiologic progression in OA patients.³⁴ These biomarker assays have been used as research tools and are currently being developed and validated as diagnostic tools for monitoring cartilage degradation or repair in OA and RA patient

populations and for assessment of treatment (see Chapters 71 and 100). Although a single marker may be insufficient, it may be possible eventually to identify a combination of biomarkers that discriminate between different stages of OA in different populations.

Repair of Articular Cartilage

Articular cartilage has a poor capacity for regeneration, and pharmacologic enhancement of cartilage repair would have considerable potential in the treatment of arthritides and intra-articular fractures. The extent of intrinsic repair of a cartilage defect depends on the depth of the lesion and whether the defect penetrates the subchondral bone plate.⁴³⁵ Repair of superficial defects occurs if the chondrocytes remain viable. Owing to the avascularity of cartilage, it differs from most other tissues in its response to injury. The vascular-dependent inflammatory and reparative phases of the classic healing response are unavailable. Partial defects generally do not regenerate because resident chondrocytes cannot migrate into the defect, and there is no vascular access for progenitor cells. Deep cartilage defects with disruption of the subchondral bone plate initiate vascular responses, however, including bleeding, fibrin clot formation, and inflammation, which permit cell invasion from the blood or underlying bone marrow. The lesion becomes filled by granulation tissue, which eventually is replaced by fibrocartilage, but rarely by true hyaline cartilage. Current procedures for cartilage repair include joint lavage, tissue débridement, microfracture of the subchondral bone, and transplantation of autologous or allogeneic osteochondral grafts, in addition to the ultimate therapy of total joint replacement.⁴³⁵ These procedures may lead to the formation of fibrous tissue, chondrocyte death, and further cartilage degeneration and have variable success rates.

Transplantation of cultured autologous chondrocytes has been used successfully to repair small, full-thickness lesions in knee cartilage in young adults with sports injuries.⁴³⁶ Evidence of successful repair has been shown by turnover and remodeling of the initial fibrocartilaginous matrix formed by transplanted chondrocytes as the result of enzyme degradation and new synthesis of type II collagen.⁴³⁷ The donor site, although not load bearing, may undergo significant morbidity and osteoarthritic changes. A randomized, controlled trial suggests little difference in efficacy compared with microfracture of subchondral bone.⁴³⁸

Major challenges for cartilage repair include restoration of the three-dimensional collagen structure and integration of the newly synthesized matrix with resident tissue.^{435,439} Novel approaches using autologous chondrocytes genetically engineered ex vivo to express anabolic factors have been explored to promote differentiation before implantation in the defect.^{232,440} Induction of the synthesis of IGF-I, TGF- β , BMP-2, and BMP-7 by gene transfer increases the synthesis of cartilage proteoglycans and collagens in cultured chondrocytes.⁴⁴¹ Many of these factors, including BMP-2, BMP-4, BMP-6, BMP-7, BMP-9, TGF- β , and CDMP-1, are able to induce chondrogenic differentiation of mesenchymal progenitor cells in vitro.^{442,443} BMP-2 and BMP-7 (OP-1) are approved for multiple indications in the area of bone fracture repair and spinal fusion and can promote cartilage repair in various models of focal cartilage

defects. The introduction of BMPs into joints via in vivo or ex vivo gene delivery or in injectable or implantable carriers has been investigated for the repair of small defects in animal models.⁴⁴⁴ Findings in vitro using BMP-2, BMP-9, and BMP-13 suggest, however, that they may serve as potent anabolic factors for juvenile cartilage, which contains chondroprogenitors, but not for adult cartilage.⁴⁴⁵

Several studies have shown that injection of free TGF- β or adenovirus-mediated delivery of TGF- β promotes fibrosis and osteophyte formation, while stimulating proteoglycan synthesis in cartilage. Based on these observations, local application of molecules that block endogenous TGF- β signaling, such as the soluble form of TGF- β RII, inhibitory SMADs, or the physiologic antagonist, latency-associated peptide-1, has been proposed as a means of blocking osteophyte formation.⁴⁴⁶ Gene transfer of combinations of anabolic factors and inhibitory cytokines combined with cartilage engineering approaches may be a long-term goal for repair of extensive defects in RA or late OA patients and for prevention of further damage. Use of bone marrow-derived chondroprogenitor cells or mesenchymal stem cells from other sources such as synovium and adipose tissue as gene delivery vehicles to the site of cartilage damage is a promising strategy for the future, although many challenges remain.

SUMMARY AND CONCLUSION

As the single cellular component in adult articular cartilage, chondrocytes are responsible for maintaining the ECM components in a low-turnover state. The composition and organization of matrix macromolecules, unique to this tissue, are determined during chondrocyte differentiation in embryonic and postnatal development of cartilage. Adult chondrocytes exist in a hypoxic environment within articular cartilage. They are inactive metabolically, partially as a result of the absence of blood vessels and nerves, and display a rounded morphology that reflects their quiescent state. Chondrocyte culture models have been developed with the aim of maintaining differentiated phenotypes, characterized by the major collagen and proteoglycan constituents, type II collagen and aggrecan. Chondrocytes interact with specific ECM components via cell surface receptors, including integrins, annexins, syndecans, DDR2, and CD44.

Studies in vitro and in vivo have shown that adult articular chondrocytes are capable of responding to biologic and mechanical stimuli that are anabolic or catabolic. Anabolic factors include members of the TGF- β /BMP family and IGF-I. Catabolic factors include proinflammatory cytokines, such as IL-1, TNF, IL-17, and IL-18, which stimulate the synthesis of matrix-degrading proteinases, such as MMPs and aggrecanases, and inhibit the synthesis of cartilage matrix proteins. Many of the signaling pathways and transcription factors that mediate the responses of chondrocytes to these factors have been elucidated, but how they orchestrate specific chondrocyte functions is complex and is not fully understood. Under physiologic conditions, the adult articular chondrocyte maintains a stable equilibrium of low-turnover replacement of matrix components. Adult chondrocytes have a poor capacity for mediating effective repair of extensive cartilage lesions, and this capacity declines with age. Age-related changes in chondrocyte function

decrease the ability of cells to maintain the tissue, including decreased synthetic activity, synthesis of smaller and less uniform aggrecan molecules and less functional link proteins, and decreased responsiveness to anabolic growth factors. Further understanding of how the adult articular chondrocyte functions within its unique environment would aid in the development of rational strategies for maintaining homeostasis and protecting against cartilage damage.

Biology, Physiology, and Morphology of Bone

GEORG SCHETT

KEY POINTS

Intramembranous or endochondral ossification generates the bone tissue.

Bones consist of a dense cortical shell and sponge-like trabecular network (cancellous bone).

Bone formation depends on metabolically active osteoblasts synthesizing matrix proteins.

Resorption of bone is mediated by multinucleated hematopoietic cells, the osteoclasts.

The most abundant cell type in bone is the osteocyte.

Bone is continuously rebuilt, a process known as *bone remodeling*.

The immune system, in particular T lymphocytes, influences bone remodeling. Neuroendocrine systems exert systemic control on bone remodeling.

STRUCTURE AND COMPOSITION OF BONE

Bone is a specialized connective tissue that serves (1) locomotion by providing the insertion site of the muscles, (2) protection of the internal organs and the bone marrow as well, and (3) metabolic function such as storage and provision of calcium to the body. Bone consists of cells and the extracellular matrix, which is composed of type I collagen fibers and a number of noncollagenous proteins. The specific composition of the bone matrix allows its mineralization, which is a specific feature of bone.

Two major types of bones exist: flat bones, which are built by intramembranous ossification, and long bones, which emerge from endochondral ossification. Intramembranous bone formation is based on the condensation of mesenchymal stem cells, which directly differentiate into bone-forming osteoblasts. In contrast, during endochondral ossification of the long bones, the mesenchymal stem cells first differentiate into chondrocytes that will further be replaced by osteoblasts. Long bones consist of the (1) epiphyses, which are protrusions at the ends of the long bones; (2) the diaphysis constituting its shaft; and (3) the metaphyses, which are located between the epiphysis and the diaphysis (Figure 4-1). The metaphysis is separated from the epiphysis by the growth plate, a proliferative cartilage layer, which is essential for the longitudinal growth of bones. After finishing growth, this cartilage layer is entirely remodeled into bone. The external shape of bones is formed by a dense cortical shell (cortical or compact bone), which is particularly strong along the diaphysis, where the bone

marrow is located. The cortical bone shell becomes progressively thinner toward the metaphyses and epiphyses, where most of the trabecular bone is located. Trabecular bone (also called *cancellous bone*) is a sponge-like network consisting of myriads of highly interconnected bony trabeculae. The outer and the inner surfaces of cortical bone are covered by layers of osteogenic cells, termed the *periosteum* and the *endosteum*, which are involved in the growth of width by bone apposition at the periosteal and bone resorption at the endosteal sites.

Although cortical and trabecular bone is composed of the same cells and same matrix components, there is a substantial difference between these two forms of skeletal tissue. Cortical bone almost exclusively consists of mineralized tissue (up to 90%), allowing it to fulfill its mechanical requirements. In contrast, only 20% of trabecular bone is mineralized tissue, whereas the bone marrow, blood vessels, and a network of mesenchymal stem cells cover the rest. As a consequence, trabecular bone shares a vast surface with the nonmineralized tissue, which is the basis for the metabolic function of bone, necessitating a high level of communication between the bone surface and the nonmineralized tissue.

Bone Matrix

The key protein component of bone is collagen type I. Collagen fibers follow specific directions forming the basis for the lamellar structure of bone. This lamellar structure, which can be visualized when examining bone in the polarized light, allows dense packaging, resulting in optimal resistance to mechanical load. The lamellar collagen structures can be assembled in parallel (e.g., along the cortical bone surfaces and inside the bony trabeculae) or concentrically around blood vessels embedded in the Haversian channels of the cortical bone. In case of rapid deposition of new bone such as during fracture healing, this lamellar structure is missing and the bone is then called *woven bone*. Woven bone is consecutively remodeled into lamellar bone, which is also considered “mature” bone. The composition of the collagen backbone also assists the deposition of spindle- or plate-shaped hydroxyapatite crystals, which contain calcium phosphate, allowing the calcification of the bone matrix.

In addition to collagen type I, other so-called noncollagenous proteins also exist in bone. Some of them such as osteocalcin, osteopontin, and fetuin are mineralization inhibitors, which serve to balance the degree of mineralization of the skeletal tissue. Aside from their intrinsic function in bone, noncollagenous proteins also exert important metabolic functions such as the control of energy metabolism by osteocalcin.

Figure 4-1 Long bones consist of the epiphyses separated by growth plates from the metaphyses, which contain most of the trabecular bone. The outer lining of bone is the dense cortical bone, which is covered by the periosteum (outer surface) and the endosteum (inner surface). The latter connects bone to the bone marrow. The bony end plates are covered by the articular cartilage, consisting of a mineralized deep zone and a nonmineralized surface zone.

Bone Cells: Osteoblasts

Osteoblasts are the bone-forming cells that derive from the mesenchymal stem cells of the bone marrow, which also form chondrocytes, myocytes, and adipocytes. Osteoblasts are cuboid-shaped cells that form clusters covering the bone surface. They are metabolically highly active, synthesizing the collagenous and noncollagenous bone matrix proteins, which are excreted and then deposited between the osteoblasts and the bone surface. This newly built matrix, which is not yet calcified, is termed the *osteoid*. The lag phase between osteoid deposition and its mineralization is approximately 10 days. Osteoblast differentiation depends on the expression of two key transcription factors, Runx2 and its target Osterix 1, which confer the differentiation of these cells into osteoblasts in response to external stimuli.¹ Prostaglandin E₂ (PGE₂), insulin-like growth factor (IGF)-1, parathyroid hormone (PTH), bone morphogenic proteins (BMPs), and Wntless and Int-1 (Wnt) proteins are key stimuli for osteoblast differentiation.^{2,3} Prostaglandin E₂, for instance, is an important anabolic factor for bone and induces the expression of bone sialoprotein and alkaline phosphatase in mesenchymal cells. Bone morphogenic proteins (BMPs) and transforming growth factor (TGF)- β , which shares structural similarities with BMPs, foster osteoblast differentiation by activating intracellular Smad proteins. Finally, Wnt proteins, a family of highly conserved signaling molecules, are potent stimulators of osteoblast differentiation. Wnt proteins bind to surface receptors on mesenchymal cells such as Frizzled and LRP5, eliciting activation and nuclear translocation of the transcription factor β -catenin, which induces the transcription of genes involved in osteoblast differentiation. Wnts thereby act not only in close synergy with BMPs but also cross-talk

to the receptor activator of nuclear factor κ B ligand (RANKL)-osteoprotegerin (OPG) system, which is involved in the differentiation and function of bone-resorbing osteoclasts.

Bone Cells: Osteocytes

Osteocytes are by far the most abundant cell type within bone. One cubic millimeter of bone contains up to 25,000 osteocytes, which are well connected with each other and the bone surface by small tubes (canaliculi) constituting a large and dense communication network inside the bone, which has similarities to the nervous system. The surface of this network of lacunae containing the osteocytes and the canaliculi containing the interconnecting filaments of the osteocytes covers an area of 1000 to 4000 square meters. Osteocytes are derived from osteoblasts, which are subsequently entrapped in the bone matrix. Osteocytes however, also start to express genes that are specific for these cells and not found in other cells such as osteoblasts. One of the most interesting products of the osteocyte is sclerostin, a secreted molecule that binds LRPs and blocks Wnt-stimulated bone formation.^{4,5} Consistent with its function as an inhibitor of bone formation, overexpression of sclerostin leads to low bone mass, whereas deletion of sclerostin leads to increased bone density and strength. Loss-of-function mutations in the human SOST gene encoding sclerostin entail increased bone mass, a disease termed *sclerosteosis*. Several local and systemic factors have been suggested as possible regulators of sclerostin expression by osteocytes. For instance, intermittent administrations of parathyroid hormone (PTH), which are associated with strong anabolic effects on the bone, potentially inhibit sclerostin expression.

Bone Cells: Osteoclasts

Osteoclasts are multinucleated cells containing up to 20 nuclei and are unique in their ability to resorb bone.^{6,7} They are directly attached to the bone surface and build resorption lacunae (Howship's lacunae). Apart from their multiple nuclei, another characteristic of the osteoclast is the *ruffled border*, a highly folded plasma membrane facing the bone matrix and designed to secrete and resorb proteins and ions into the space between the osteoclast and bone surface (Figure 4-2). The space between this ruffled border and the bone surface is the place where bone resorption occurs. It is sealed by a ring of contractible proteins and tight junctions because it represents one of the few regions of the human body, where a highly acidic milieu is found. Bone degradation by osteoclasts comprises two major steps: first, demineralization of inorganic bone components, and second, removal of organic bone matrix. To demineralize bone, osteoclasts secrete hydrochloric acid through proton pumps into the resorption lacunae. This proton pump requires energy, which is provided by an ATPase allowing the enrichment of protons in the resorption compartment, which, in fact, represents an extracellular lysosome. In addition to protons and chloride, osteoclasts release matrix-degrading enzymes including tartrate resistant acid phosphatase (TRAP), lysosomal cathepsin K, and other cathepsins. Cathepsin K can effectively degrade collagens and other bone matrix proteins. Consequently, inhibitors of cathepsin K block osteoclast function and slow down bone resorption.

Osteoclasts originate from hematopoietic monocytic precursor cells and, upon the influence of specific signals, undergo a series of differentiation steps to become mature osteoclasts. Essential signals for osteoclast differentiation

are macrophage colony stimulating factor (M-CSF) and RANKL. During this differentiation and maturation process, osteoclasts acquire specific markers such as TRAP, fuse to multinucleated giant cells, and polarize on contact to bone. Osteoclastogenesis depends on an adequate microenvironment, which provides essential signals such as M-CSF and RANKL and also certain cytokines like tumor necrosis factor (TNF), which further enhance osteoclast differentiation. Mesenchymal cells such as preosteoblasts express M-CSF and RANKL and can induce osteoclast formation highlighting the close interaction between bone formation and bone resorption.

RANKL, a TNF super family member, is a surface molecule expressed by a large set of different cell types including preosteoblasts and activated T cells.⁸ Under steady-state conditions its expression is induced in cells of the osteoblastic lineage in response to osteotropic factors such as vitamin D, parathyroid hormone, and prostaglandins. Moreover, inflammatory cytokines such as TNF, interleukin (IL)-1, and IL-17 can induce RANKL expression.⁹⁻¹² RANKL is essential for the final differentiation steps of osteoclasts, as well as for their bone-resorbing capacity by engaging its receptor RANK on monocytic osteoclast-precursor cells. The interaction of RANKL with its receptor RANK is modulated by OPG, a secreted glycoprotein, which was identified as a soluble factor that strongly suppresses osteoclast differentiation both in vitro and in vivo. Interestingly, OPG expression is induced by estrogens, which explains the increase in osteoclast numbers and enhanced bone resorption during menopause. In accordance, RANKL-deficient mice display severe osteopetrosis due to the lack of osteoclasts. Regarding the central role of the RANKL-RANK-OPG signaling system in bone resorption, researchers are increasingly interested in the therapeutic targeting of this

Figure 4-2 Osteoclasts form from mononuclear precursors (colony-forming unit macrophages [CFU-M]), which differentiate into mononuclear osteoclast precursors. These cells fuse and build a polykaryon, forming a preosteoclast. Final differentiation is characterized by cell polarization and acquisition of a ruffled border. M-CSF, macrophage colony-stimulating factor; RANKL, receptor activator of nuclear factor κ B ligand; TRAP, tartrate resistant acid phosphatase.

system in human disease and recent clinical trials on postmenopausal osteoporosis have revealed the potent antiresorptive effect of a neutralizing RANKL antibody (denosumab).¹³ Beyond RANKL-RANK interactions, other important pro-osteoclastogenic signaling pathways are based on the triggering receptor expressed on myeloid cells (TREM) 2, which interacts with the tyrosine kinase DAP12 and the osteoclast-associated immunoglobulin-like receptor (OSCAR). Both molecules are strong enhancers of osteoclastogenesis.¹⁴

Bone Remodeling Process

Developmental bone growth, postdevelopmental maintenance and repair of bone, and provision of calcium from the bone depend on a dynamic process called *bone remodeling* (Figure 4-3). Yet unknown factors, which may likely be of mechanical nature and sensed by the osteocytes, initiate bone remodeling at a specific site. Death of osteocytes and the resulting metabolic changes leading to a lack of silencers for bone turnover, like sclerostin, may govern this activation process. It is followed by a resorptive phase dominated by osteoclast-mediated degradation of the bone matrix resulting in a resorption lacuna. The naked bone surface inside this lacuna is subsequently populated by mesenchymal cells immigrating from the neighboring bone surface, which start differentiating into osteoblasts and produce the new bone matrix (also termed *osteoid*). This matrix then mineralizes, and the bone returns to its resting state again. This entire bone remodeling process takes about 3 to 6 months. Adults continuously remodel their skeleton, a process that runs even faster in childhood and adolescence. In adults, it takes 7 to 10 years to remodel the entire skeleton, indicating that we fully replace it several times during our lifetime. Most of the bone remodeling happens in the trabecular bone, which promotes the building of an optimal inner microstructure adapted to the individual mechanical demands. Trabecular bone is the leading structure in the

vertebral bodies (up to two thirds of the bone substance) and in long bones such as the femurs (about 50% of the bone substance).

Normal physiologic circumstances ensure a balance between bone formation and bone resorption to maintain skeletal homeostasis. This bone remodeling process requires a tight mutual regulation of bone resorption by osteoclasts and bone formation by osteoblasts, a phenomenon called *coupling*. Coupling is regulated on at least three different levels: (1) by a direct interaction between osteoblasts and osteoclasts, (2) by local interactions between the immune system and bone cells, and (3) by neuroendocrine systemic control of bone metabolism.

Direct Interactions between Osteoblasts and Osteoclasts

A proper coupling between bone formation and bone destruction is essential to maintain bone integrity (Figure 4-4). This coupling process involves two main mechanisms. The first one is the expression of the essential pro-osteoclastogenic cytokines by the osteoblast lineage, and the second one involves the ephrin ligand/ephrin receptor bidirectional signaling.^{15,16} Preosteoblasts are the main pro-osteoclastogenic cells in normal physiologic conditions providing the first level of coupling between bone formation and bone resorption. In response to Wnt signaling, osteoblasts slowly lose their supportive activity for osteoclasts when maturing toward more mineralizing cells and then becoming the bone-embedded osteocytes. They will then secrete antiosteoclastogenic molecules such as OPG and the Wnt inhibitors sclerostin, dickkopf-1, and secreted frizzled-related protein 1 (SFRP1), which either block osteoclast differentiation (OPG) or also inhibit the further differentiation of osteoblasts. A second level of coupling involves the expression of ephrin ligands on the surface of osteoclast progenitors that can bind to ephrin receptors and activate their tyrosine kinase activity. Two ephrin ligands regulate

Figure 4-3 Sequence of bone remodeling with *activation* characterized by sensing of damage by osteocytes, *resorption* by osteoclast differentiation and removal of bone matrix, *migration* of bone-lining mesenchymal cells into the lacuna, *formation* of new matrix by osteoblasts (cuboid cells), and *mineralization* of the newly synthesized matrix.

Figure 4-4 Mesenchymal stem cells and preosteoblasts generated macrophage colony-stimulating factor (M-CSF) and receptor activator of nuclear factor κ B ligand (RANKL) supporting osteoclast differentiation. In contrast, mature osteoblasts suppress osteoclast differentiation by expression of osteoprotegerin (OPG) and secreted frizzled-related protein 1 (SFRP1). The ephrin-A2 system is an autocrine stimulator for osteoclasts and also blocks bone formation. In contrast, ephrin-B2 binding to its receptor ephrin-B4 stimulates osteoblast differentiation. Osteocyte-derived mediators such as sclerostin (SOST) and dickkopf-1 (DKK-1) suppress bone formation by inhibiting the Wnt pathway.

bone remodeling. The first, ephrin-B2, binds to the receptor EphB4 on osteoblast progenitors, increasing their differentiation and stimulating bone formation. The second, ephrin-A2, acts in an autocrine manner by binding to the EphA2 receptor on the osteoclasts, promoting their differentiation in a paracrine manner on the osteoblasts, inhibiting their differentiation.

Bone Remodeling by the Immune System

The reciprocal regulation of osteoblast and osteoclast differentiation, as well as local immune cells, regulate bone remodeling. This interaction, which experts in the field of osteoimmunology have recently examined extensively, is highly relevant for pathologic bone remodeling as observed in postmenopausal osteoporosis and inflammatory diseases.¹⁷⁻¹⁹ The first hint for a link between lymphocytes and osteoclastogenesis came from the identification of RANKL, which is also expressed by activated T cells and promotes dendritic cells' survival.²⁰ RANKL expression was found on the various subsets of proliferative T cells (CD8 and CD4, Th1 and Th2), as well as on FoxP3-expressing regulatory T cells (Tregs).

Despite consistent expression of RANKL on various T cell lineages, individual T cells exert different function on the osteoclast, which depend on their cytokine and surface molecule expression pattern. For instance, Th17 cells stimulate osteoclast differentiation via the production of IL-17, which stimulates the synthesis of pro-osteoclastogenic molecules such as RANKL on mesenchymal cells. However, T cells can also secrete or express strong inhibitors of osteoclastogenesis such as OPG, interferon (IFN)- γ , IL-4, or CTLA-4.²¹⁻²³ Indeed, Th1 cells repress rather than stimulate

osteoclastogenesis by the expression of IFN- γ . Moreover, regulatory T cells effectively block osteoclast differentiation by the expression of CTLA-4, a molecule that blocks T cell co-stimulation.²⁴

Systemic Control of Bone Remodeling by Neuroendocrine Mechanisms

Bone remodeling is regulated not only locally but also by various systemic hormonal pathways including the sex hormone and the growth hormone (GH)/insulin-like growth factor (IGF) axes. In addition, two major systemic neuroendocrine regulators of bone homeostasis co-regulate bone, fat, and energy metabolism.^{25,26} The two central players of this systemic loop seem to be osteocalcin and leptin. Osteocalcin is a hormone produced by mature osteoblasts and acts on the β cells of the pancreas to stimulate proliferation and thus insulin production in response to leptin.²⁶ In addition, osteocalcin can directly stimulate adipocytes to regulate insulin sensitivity. Leptin is a peptide hormone produced by adipocytes of the white adipose tissues. Its deficiency is causing obesity and increased bone mass. Although the increased fat mass is certainly linked to the role of leptin in controlling appetite, the effect of leptin on bone and fat can be dissociated. Indeed, bone formation is negatively regulated by leptin through a hypothalamic pathway: the β -adrenergic sympathetic nervous system that mediates decreased osteoblast proliferation via the induction of clock genes in osteoblasts.^{27,28} How leptin regulates bone formation is debated. However, two potential hypothalamic relays have been identified. The first one is the NPY peptide, a repressor of bone formation, that is silenced by leptin.²⁹ The second downstream modulator of leptin is

neuromedin U, which inhibits clock gene expression and increases osteoblast proliferation.³⁰ These observations suggest that disturbance of the metabolic loops linking adipogenesis, osteogenesis, and insulin production have profound consequences on bone homeostasis.

CONCLUSION

Bone is continuously remodeled by bone-resorbing osteoclasts and bone-forming osteoblasts. This remodeling process allows the optimal adaptation of the bone architecture to individual demands and tight control of calcium homeostasis. Local factors control the bone remodeling process on the basis of osteoclast-osteoblast interactions, as well as by systemic immune and neuroendocrine factors controlling the bone-resorbing and bone-forming cells.

KEY POINTS

The structure and function of skeletal muscle and its neural recruitment pattern can change rapidly in response to activity level (i.e., plasticity).

The smallest functional unit of muscle, the sarcomere, is composed of an almost crystalline array of filamentous proteins that convert metabolic energy into force and movement.

Muscles are connected to the skeleton through collagenous tendons.

Skeletal muscle contraction is controlled by the central nervous system through depolarization of specific efferent neurons called *motor neurons*.

Motor neurons innervate and depolarize muscle fibers through cholinergic synapses called *neuromuscular junctions*.

Afferent neurons provide the central nervous system with sensory information required for effective control of movement and posture.

Force is transmitted to the exterior through two sets of protein cell adhesion complexes: integrins and dystroglycans.

Approximately 660 skeletal muscles support and move the body under the control of the central nervous system. They constitute up to 40% of adult human body mass. Most skeletal muscles are fastened by collagenous tendons across joints in the skeleton. The transduction of chemical energy into mechanical work by muscle cells leads to muscle shortening and consequent movement. A high degree of specialization in this tissue is evident from the intricate architecture and kinetics of intracellular membrane systems, the contractile proteins, and the molecular components that transmit force extracellularly to the basement membrane and tendons. Muscle cells normally exhibit wide variations in activity level and are able to adapt in size, isoenzyme composition, membrane organization, and energetics. In pathologic states, they often become deconditioned. These examples of plasticity can be surprisingly swift and extensive. This chapter outlines the structure and function of muscle and its relationship to associated connective tissue. It also introduces the basis for the highly adaptive response to altered functional demands and diseases. Two excellent Web sites can be accessed for further information in these areas.^{1,2}

STRUCTURE

Muscle Tissue

Parallel, aligned bundles of skeletal muscle fibers make up approximately 85% of muscle tissue and consist of a variety of signaling and contractile proteins (Table 5-1). Nerves, blood supply, and connective tissue structures that provide support, elasticity, and force transmission to the skeleton (see later discussion) constitute the remaining volume. Muscle fibers range in length from a few millimeters to 30 cm and in diameter from 10 to 500 μm , with a typical length of 3 cm and diameter of 100 μm . This elongated shape is determined by the organization of the contractile proteins that occupy most of the sarcoplasm. Each muscle has a limited range of shortening that is amplified into large motions by lever systems of the skeleton, usually operating at a mechanical disadvantage. Variations in geometric arrangements of the fibers—parallel, convergent (fan-shaped), pennate (feather-like), sphincter (circular), or fusiform (thick in the middle with tapered ends)—determine some of the mechanical properties. For example, a muscle with fibers aligned parallel to the force-generating axis will have more basic contractile units (i.e., sarcomeres as discussed later) in series than a similarly sized pennate muscle, allowing the parallel muscle to contract quicker, but with less force, than the pennate muscle. Muscles designed for strength (e.g., gastrocnemius) are typically pennate, whereas those designed for speed (e.g., biceps) tend to have parallel fibers. Muscles are commonly arranged around joints as antagonistic pairs facilitating bidirectional motion. When one muscle (the agonist) contracts, another (its antagonist) is relaxed and passively extended. Their roles reverse to actively generate the opposite motion, unless it occurs passively by the force of gravity.

An extensive network of areolar connective tissue, forming the endomysium, surrounds each muscle fiber. Fine nerve branches and small capillaries, necessary for the exchange of nutrients and metabolic waste products, penetrate this layer. The endomysium is continuous with the perimysium, a connective tissue network that ensheathes small parallel bundles of muscle fibers known as *fasciculi*, *intrafusal fibers*, *larger nerves*, and *blood vessels*. The epimysium encompasses the whole muscle. All three layers of connective tissue contain collagen, mostly types I, III, IV, and V, with types IV and V predominating in the basement membranes surrounding each skeletal muscle fiber. The $\alpha 1(\text{I})\alpha 2(\text{I})$ -chain composition of the collagen IV isoform is the most prevalent and provides the mechanical stability and flexibility of the basal lamina^{3,4} (see Chapter 2). The perimysium and endomysium merge at the junction between muscle fibers and tendons, aponeuroses, and fasciae. These

Table 5-1 Signaling and Contractile Proteins of Skeletal Muscle

Protein	Molecular Weight (kD)	Subunits (kD)	Location	Function
Acetylcholine receptor	250	5 × 50	Postsynaptic membrane of neuromuscular junction	Neuromuscular signal transmission
Annexins	38	—	F-actin-binding protein	Membrane repair
Dihydropyridine receptor	380	1 × 160 1 × 130 1 × 60 1 × 30	T-tubule membrane	Voltage sensor
Dysferlin	230	—	Periphery of myofibers	Membrane repair
Ryanodine receptor	1800	4 × 450	Terminal cisternae of SR	SR Ca ²⁺ release channel
Ca ²⁺ ATPase	110	—	Longitudinal SR	Uptake of Ca ²⁺ into the SR
Calsequestrin	63	—	Lumen of SR terminal cisternae	Binding and storage of Ca ²⁺
Troponin	70	1 × 18 1 × 21 1 × 31	Thin filament	Regulation of contraction
Tropomyosin	70	2 × 35	Thin filament	Regulation of contraction
Myosin	510	2 × 220 2 × 15 2 × 20	Thick filament	Chemomechanical energy transduction
Actin	42	—	Thin filament	Chemomechanical energy transduction
MM creatine phosphokinase	40	—	M line	ATP buffer, structural protein

layers give the attachment sites great tensile strength and distribute axial force into shear forces over a larger surface area.

Fiber Types

Muscles adapt to their specific functions. In any given muscle, part of this adaptation arises from its composition and organization of fiber types. Human skeletal muscle fibers can be classified according to their myosin heavy chain (MHC) isoform (I, IIA, or IIX). MHC molecules break down adenosine triphosphate (ATP) to produce the energy necessary for muscle contraction. The rate of ATP breakdown, or adenosine triphosphatase (ATPase) rate, of the MHC isoforms is I < IIA < IIX, leading to contractions that are relatively slow in MHC I fibers, fast in MHC IIA fibers and very fast in MHC IIX fibers. ATP synthesis primarily occurs through aerobic respiration (oxygen required) in MHC I or slow oxidative fibers; this is aided by their having more mitochondria, an increased capillary blood supply, and more myoglobin compared with MHC IIX, or fast glycolytic fibers that use anaerobic respiration (oxygen not required) to restore their ATP levels. MHC I fibers produce less power than MHC IIX fibers but are more resistant to fatigue. MHC IIA or fast oxidative-glycolytic fibers can use aerobic and anaerobic respiration and fall in between I and IIA fibers in terms of mitochondria, blood supply, myoglobin, power output, and fatigability. Although most human skeletal muscles contain a mixture of fiber types, MHC I fibers are more prominent in muscles used for posture and endurance, and MHC IIX fibers dominate in muscles used for quick movements of short duration. Notably, individual fibers can contain a mixture of MHC isoforms, leading to six different

fiber types in humans (“pure”: MHC I, IIA, IIX; “mixed”: MHC I/IIA, IIA/IIX, I/IIA/IIX), which allow for a wide range of contractile properties. A list of various attributes of MHC isoforms can be found in [Table 5-2](#).

During development, fiber-type specificity may be partially determined before innervation.⁵ Although the biologic events and signals responsible for designating functional specialization in muscle fibers are not fully understood, classic cross-innervation experiments demonstrated that innervation can dynamically specify and modify the type of muscle fiber.⁶ After cross-innervation, the functional and histologic properties listed in [Table 5-2](#) shift toward the target fiber type over a few weeks’ time, indicating the ability of muscles to adapt and remodel in accordance with the pattern of neuronal activity.

EVENTS DURING MUSCLE CONTRACTION

Neural Control

Voluntary control of muscle activation is a complex process. Afferent neurons emanating from sensory organs, such as cutaneous mechanoreceptors and thermoreceptors, pain receptors, joint receptors, and tendon organ and muscle spindles, provide the central nervous system (CNS) with stimuli in the form of action potentials that, with or without additional stimuli from the brain, provide the necessary information for feedback control of effector organs via efferent neurons.⁷ Efferent neurons are specifically called *motor neurons* if their axons innervate muscle. Many times, more afferent than efferent neurons afford effective feedback control of movement and posture. The afferent and efferent neurons are accompanied by Schwann cells, which are glial

Table 5-2 Classification of Muscle Fiber Types by Myosin Heavy Chain Isoform

General Features	MHC I	MHC IIA	MHC IIX
Mitochondria	Many	Intermediate	Few
Capillary blood supply	Extensive	Moderate	Moderate
SR membrane	Sparse	Extensive	Extensive
Z line	Wide	Moderate	Narrow
Protein Isoforms			
Myosin essential light chain (ELC)	Slow and Fast	Fast	Fast
Myosin regulatory light chain (RLC)	Slow and Fast	Fast	Fast
Myosin binding protein-C (MBP-C)	Slow	Fast	Fast
Thin filament regulatory proteins	Slow	Fast	Fast
Mechanical Properties			
SR calcium ATPase rate	Slow	Fast	Fast
Actomyosin ATPase rate	Slow	Fast	Very Fast
Contraction time	Slow	Fast	Very Fast
Shortening velocity	Slow	Fast	Very Fast
Power production	Low	Moderate	High
Resistance to fatigue	High	Moderate	Low
Metabolic Profile			
Oxidative capacity	High	Moderate	Low
Glycolytic capacity	Moderate	High	High
Glycogen	Low	High	High
Myoglobin	High	Moderate	Low

ATPase, adenosine triphosphatase; MHC, myosin heavy chain; SR, sarcoplasmic reticulum.

cells residing in the peripheral nervous system.⁸ Neurons are termed *myelinated* if Schwann cells wrap around the axon at regularly spaced intervals. The points of bare axon between these Schwann cells are called *nodes of Ranvier*. Myelination enhances the velocity of action potential propagation by compelling a saltatory conduction of the action potential between neighboring nodes. Schwann cells may also fully or nearly fully cover the axon, thus rendering the neuron unmyelinated and relatively slow in action potential propagation. Three groups of myelinated motor neurons (α , β , γ) are distinguished by diameter, propagation velocity, and target fiber type. Skeletal muscle fibers typically are innervated at several neuromuscular junctions along their length by branches of an α -motoneuron (largest and fastest) or β -motoneuron (Figure 5-1). Muscle spindles are innervated by β - or γ -motoneurons, in addition to the afferent system, for sensing muscle length and force. A single motor neuron and the muscle fibers it innervates constitute a motor unit. When a motor neuron is excited, all fibers in the motor unit are triggered to contract simultaneously. A motor unit responsible for fine movement contains few muscle fibers, but motor units for gross movement generally contain many fibers. The level of muscle activation is controlled from the CNS by the number of motor units recruited and the stimulus rate.⁹ Stimulus rate can be so infrequent as to elicit single muscle twitches, such as occur with the monosynaptic stretch reflex involving patellar tendon stretch and quadriceps activation, or conversely so frequent that individual twitches effectively fuse, causing nearly continuous activation of muscle force.¹⁰

Neuromuscular Transmission

At the neuromuscular junction, the axon tapers, loses its myelin sheath, and ends as a presynaptic terminal crowded with vesicles containing the neurotransmitter

Figure 5-1 Neuromuscular junction. **A**, Scanning electron micrograph of an α -motoneuron innervating several muscle fibers in its motor unit. Calibration bar = 10 µm. **B**, Transmission electron micrograph. Calibration bar = 1 µm. acetylcholine. The postsynaptic membrane of the muscle is indented into folds that increase its surface area and the number of nicotinic acetylcholine-receptors bound therein (see Figure 5-1). The junctional cleft is a 20- to 40-nm-wide space between the presynaptic and postsynaptic membranes.¹¹ When the motor neuron action potential reaches the presynaptic terminal, local voltage-gated Ca^{2+} channels open and extracellular Ca^{2+} streams into the terminal. Within milliseconds of Ca^{2+} influx, the acetylcholine-loaded vesicles fuse with the presynaptic membrane.¹² Exocytosed acetylcholine rapidly diffuses across the junctional cleft and binds to the nicotinic acetylcholine receptors, which in turn open Na^+ and K^+ channels of the postsynaptic membrane. The membrane is locally depolarized. An action potential is initiated and propagates along the muscle membrane (sarcolemma) at velocities up to 5 m/sec.

Excitation-Contraction Coupling

A network of tubules invaginate the sarcolemma and run deep into the muscle fiber. This transverse tubule network (T-tubules) pervades the fiber at regular intervals coinciding with sarcomere boundaries along the length of the muscle and surrounds the contractile apparatus with connected longitudinal and lateral segments (Figure 5-2). The lumen of this network is open to the extracellular space, and it contains high Na^+ and low K^+ concentrations of interstitial fluid.¹³ Action potentials at the surface membrane invade the entire T-tubular system. A specialized type of endoplasmic reticulum forms an entirely intracellular membrane system termed the *sarcoplasmic reticulum* (SR). Prevalent structures containing a T-tubule flanked by two terminal cisternae of the SR to form junctional complexes are termed *triads* (see Figure 5-2). Terminal cisternae contain oligomers of the Ca^{2+} -binding protein calsequestrin that provide the fiber with an internal reservoir of calcium ions. Ca^{2+} channels, termed *dihydropyridine receptors* (DHPRs), are localized in the T-tubule membranes facing the cytoplasmic domain of SR Ca^{2+} release channels, also called *ryanodine receptors* (RyRs), in the terminal cisternae membranes.¹⁴ These membrane proteins are further characterized in Table 5-1.

When an action potential depolarizes the T-tubular membrane, the DHPRs, primarily voltage sensors in skeletal muscle, transfer a signal from the T-tubules to the RyRs by direct interprotein coupling. Ca^{2+} is then released cooperatively through the RyRs from the SR into the myoplasm, where it activates the contractile machinery.¹⁵ This sequence of events is termed *excitation-contraction coupling*.

Mutations in the α -subunit of the DHPR in dysgenic mice lead to paralysis, because in these mutants, depolarization of the skeletal muscle membrane does not initiate release of Ca^{2+} from the SR. Excitation-contraction coupling can be restored in cultured cells from these mice by transfection with complementary DNA encoding for the DHPR,¹⁶ and transfections using chimeric constructs¹⁷ have pinpointed the domain within the DHPR that specifies skeletal- or cardiac-type excitation-contraction coupling.¹⁸ Isoforms of the RyRs also help determine the characteristics of coupling between T-tubules and the SR.¹⁹ Channelopathies in human skeletal and heart muscle have been linked to DHPR mutations.^{20,21} Human malignant hyperthermia occurs in individuals with mutant RyRs that become trapped in the open state after exposure to halothane anesthetic agents.²²

Contractile Apparatus

The specific locations and functions of the contractile proteins are listed in Table 5-1. Myofibrils (Figure 5-3D) are long, 1- μm -diameter cylindrical organelles that contain the contractile protein arrays responsible for work production, force generation, and shortening. Each myofibril is a column of sarcomeres, the basic contractile units, which are approximately 2.5 μm in length and are delimited by Z lines (Figure 5-3D and E) containing the densely packed structural protein α -actinin. The contractile and structural proteins within each sarcomere form a highly ordered, nearly crystalline lattice of interdigitating thick and thin myofilaments²³ (Figure 5-3E, I, and J). Myofilaments are remarkably uniform in both length and lateral registration, even during contraction,²⁴ resulting in the cross-striated histologic appearance of skeletal and cardiac muscles. This

Figure 5-2 Membrane systems that relay the excitation signal from the sarcolemma to the cell interior. In the electron micrograph, two T-tubules are cut in cross-section. Electron densities spanning the gap between T-tubules and sarcoplasmic reticulum membranes are the ryanodine receptors, channels that release calcium into the myoplasm. (From Alberts B, Bray D, Lewis J, et al: *Molecular biology of the cell*, ed 2, New York, 1989, Garland Publishers. Micrograph courtesy Dr. Clara Franzini-Armstrong, University of Pennsylvania, Philadelphia.)

The myofibril (**D**) shows the banding pattern created by the lateral alignment of myofilaments (**I** and **J**) within the sarcomeres (**D** and **E**). Diagrams **F** to **H** show the cross-sectional structure of the filament lattice at various points within the sarcomere. Myosin is shown at the single two-headed molecule level (**K**), and the crystal structure of the globular motor domain is shown (**L** and **S-1**) with the essential and regulatory light chains. (From Juanqueira LC, Carneiro J, Long JA: Basic histology, ed 5, Norwalk, Conn, 1986, Appleton-Lange. Modified from Bloom W, Fawcett DW: A textbook of histology, ed 10, Philadelphia, 1975, WB Saunders; Rayment I, Rypniewski WR, Schmidt-Base K, et al: Three-dimensional structure of myosin subfragment-1: a molecular motor, Science 261:50–58, 1993.)

highly periodic organization has facilitated biophysical studies of muscle by sophisticated structural²³ and spectroscopic techniques.^{25,26}

Thick filaments (1.6- μm long) containing the motor protein myosin are located in the center of the sarcomere in the optically anisotropic A band (Figure 5-3D). These thick filaments are organized into a hexagonal lattice

stabilized by M protein²⁷ and muscle-specific creatine phosphokinase²⁸ in the M line (Figure 5-3D and E). Myosin (Figure 5-3K) is a highly asymmetric 470-kD protein containing two 120-kD globular NH_2 -terminal heads, termed cross-bridges or subfragment-1 (S1) (Figure 5-3L), and an α -helical coiled-coil rod, light meromyosin (Figure 5-3K). Two light chains, essential and regulatory, ranging from 15

to 22 kD, are associated with the heavy chain in each S1 (Figure 5-3L). The rod portions of approximately 300 myosin molecules polymerize in a three-stranded helix to form the backbone of each thick filament (Figure 5-3J). The cross-bridges, protruding from these backbones, contain ATPase and actin-binding sites responsible for the conversion of chemical energy into mechanical work. Besides their role in muscle contraction, at least 20 classes of nonmuscle myosins accomplish diverse tasks in cell motility such as chemotaxis, cytokinesis, pinocytosis, targeted vesicle transport, and signal transduction.²⁹ Thus myosin is the target for mutations leading to a number of inherited muscle and neurologic diseases.^{30,31}

Thin filaments (Figure 5-3I) are double-stranded helical polymers of actin that extend 1.1 μm from each side of the Z line and occupy the optically isotropic I band (Figure 5-3D and E). A regulatory complex containing one tropomyosin molecule and three troponin subunits (TnC, TnT, and TnI) is associated with each successive group of seven actin monomers along the thin filament (Figure 5-3I).²³ In the region where the thick and thin filaments overlap, the thin filaments are positioned within the hexagonal lattice equidistant from three thick filaments (Figure 5-3F). Both sets of filaments are polarized. In an active muscle, an interaction between the two filaments causes a concerted translation of the thin filaments toward the M line that shortens the sarcomere, and thus the muscle fiber and whole muscle (Figure 5-3A through D). Actin is ubiquitous in the cytoskeleton of eukaryotic cells and, like myosin, fulfills many roles in determining cell shapes and motions.^{32,33} Control of

the actin cytoskeleton and diseases due to mutations in actin-binding proteins are being intensively investigated.³⁴

Two of the largest identified muscle proteins, titin and nebulin, function in assembly and maintenance of the sarcomeric structure. Individual titin molecules (≈ 3000 kD) are associated with the thick filament and extend from the M line to the Z line.³⁵ Titin contains repeating fibronectin-like immunoglobulin and unusual proline-rich domains that confer molecular elasticity on the resting sarcomere.³⁶ Nebulin (≈ 800 kD) is associated with the Z line and thin filaments.³⁵ Protein connections from the contractile apparatus through the sarcolemma to the extracellular matrix are described later in this chapter. The cytoskeleton of muscle fibers also contains cytoplasmic actin, microtubules, and intermediate filaments.³⁷

Force Generation and Shortening

At rest, the thin filament regulatory proteins, troponin and tropomyosin, inhibit contraction (Figure 5-3I). During a twitch, Ca^{2+} released from the SR binds to TnC, relieving this inhibition and thus allowing cross-bridges to attach to actin. A contraction results from cyclic interaction between actin and myosin (the cross-bridge cycle) that produces a relative sliding force between thin and thick filaments.³⁸ The energy source is the hydrolysis of adenosine triphosphate (ATP) to adenosine diphosphate (ADP) and orthophosphate (P_i).

A simplified model of the chemomechanical events in the cross-bridge cycle is illustrated in Figure 5-4. Motor

Figure 5-4 The actomyosin cross-bridge cycle. Myosin molecules normally have two globular head regions (cross-bridges), but for clarity only one is shown. The X within the globular domain of myosin represents a hinge point with maximum flexibility. Each head binds with two actin monomers. The sequence of reactions consists of attachment (a); the force-generating transition (b); P_i release (c); force generation and filament sliding (d); ADP release (e); ATP binding and detachment (f); and ATP hydrolysis (g). The shadowed heads near detached and force-generating myosin heads indicate high mobility of cross-bridges in these states. ADP, adenosine diphosphate; ATP, adenosine triphosphate; P_i , inorganic phosphate.

proteins, including myosin, can now be studied by single molecule biophysical techniques, which provide unprecedented detail on their dynamics.³⁹ When Ca^{2+} is present, a complex of myosin, ADP, and P_i attaches to the thin filament (step a), and structural change within the myosin S1 initiates force production and the release of P_i (steps b and c).^{40,41} The conformational change in the cross-bridge that leads to force generation is a tilting motion of the light chain region.^{42,43} Filament sliding leading to shortening of the sarcomere occurs during a strain-dependent transition between two ADP states (step d). After ADP is released (step e), ATP binds to the active site and dissociates myosin from actin (step f). Myosin then hydrolyzes ATP (step g) to form the ternary myosin–ADP– P_i complex, which can reattach to actin for the next cycle.

If the mechanical load on the muscle is high, the contractile apparatus produces a force without changing length (an isometric contraction). If the load is moderate, the thin filaments slide actively toward the center of the sarcomere, resulting in shortening of the whole muscle. The width of the muscle increases during shortening, so the volume stays constant. Work production (concomitant force and sliding) is associated with an increase in the ATPase rate. Thermodynamic efficiency (mechanical power divided by energy liberated by ATPase activity) approaches 50%—a remarkable figure given that manufactured combustion engines seldom achieve efficiencies greater than 20%.

Relaxation

The twitch is terminated by reversal of all steps in the activation. Ca^{2+} released from the SR is taken up again by Ca^{2+} -ATPase pumps located in longitudinal membranes of the SR. The myoplasmic Ca^{2+} concentration then decreases, and Ca^{2+} dissociates from TnC, deactivating the thin filament. When the number of attached cross-bridges declines below a certain threshold, tropomyosin inhibits further cross-bridge attachment, and tension declines to the resting level. Ca^{2+} diffuses within the longitudinal SR to calsequestrin sites in the terminal cisternae, ready to be released in the next twitch. Myosin continues to hydrolyze ATP at a low rate in relaxed muscle, accounting for a sizable proportion of basal metabolism.

TRANSMISSION OF FORCE TO THE EXTERIOR

Cell-Matrix Adhesions

The muscle cell is closely connected to the basal lamina along its entire surface. Several transmembrane macromolecular complexes link the myofibrils and actin cytoskeleton to laminins and collagen in the extracellular matrix. Attachment complexes for muscle, analogous to the focal adhesions of motile and epithelial cells and to the adhesion plaques and intercalated disks in cardiac muscle, contain filamentous actin, vinculin, talin, and integrin (primarily the $\alpha 7\beta 1$ isoform), which is the transmembrane link to laminin (Figure 5-5). In muscle, the main laminin isoforms are laminin-2 ($\alpha 2\beta 1\gamma 1$) and laminin-4 ($\alpha 2\beta 2\gamma 1$), which collectively are termed *merosin*. In addition to providing mechanical coupling between the cytoskeleton and the

extracellular matrix, the laminin-integrin system may provide a signaling pathway to regulate localized protein expression.⁴⁴ Defects in the expression of many of the cytoskeletal proteins lead to various forms of muscular dystrophy as summarized in Table 5-3.⁴⁵

A specialized linkage between the cytoskeleton and the basal lamina in muscle, complementary to the integrin focal adhesion system, is the dystrophin-glycoprotein complex (see Figure 5-5). Dystrophin, a 427-kD peripheral cytoskeletal protein, has been postulated to function as a mechanical link between the cytoskeleton and the cell membrane or as a shock absorber, or to contribute mechanical strength to the membrane. Its absence or truncation causes Duchenne and Becker muscular dystrophies.⁴⁶ The N-terminus of dystrophin binds to actin via a region with sequence homology to the actin-binding domain of α -actinin. This end of the dystrophin molecule may be linked to the basal lamina via the same proteins described previously for focal adhesion-like complexes (see Figure 5-5). The C-terminus binds to a transmembrane dystroglycan-sarcoglycan complex, which in turn binds to the laminins. Muscular dystrophies of varied severity are associated with loss of these components (see Table 5-3).⁴⁷ Dystroglycans are also required for early embryonic development of muscle, possibly organizing laminin localization and assembly.^{48,49} Utrophin, a smaller dystrophin-related protein (395 kD), may also link the actin cytoskeleton to the dystroglycans, especially near the neuromuscular junction and in nonmuscle cells. Overexpression of this protein or truncated dystrophin constructs are promising avenues for gene therapy in Duchenne muscular dystrophy.⁵⁰ The unusual intricacy of cell-matrix connection systems in muscle may relate to the high forces generated during contraction.

Myotendinous Junction

The force of muscle contraction is transmitted to the skeleton via the tendons, which are composed of collagens type I and III, blood vessels, lymphatic ducts, and fibroblasts. At the ends of the muscle fibers, myofibrils are separated by invaginations of sarcolemma filled with long bundles of collagen arising from the tendon. These membrane folds increase the surface area for bearing the mechanical load by approximately 30-fold. Instead of terminating in the Z disks, actin filaments insert into a subsarcolemmal matrix containing α -actinin, vinculin, talin, and integrin. The force is transmitted through laminin to the collagen of the tendon.

ENERGETICS

Metabolic pathways in muscle cells are specialized for the variable, at times extreme, rates of ATP splitting by the contractile apparatus and membrane ionic pumps. Among the dozens of metabolic enzymes present, only the most important ones with regard to normal muscle function are mentioned here.

Buffering of Adenosine Triphosphate Concentration

The ATP content (≈ 5 mM) is sufficient for only a few seconds of contraction, so rapid and effective buffering of

Figure 5-5 Connections between the muscle cytoskeleton and the extracellular matrix. Actin is linked through integrins to the matrix, as in many cell types. Dystrophin forms an extra link through the dystroglycan-sarcoglycan complex of glycosylated proteins. The helical section of dystrophin is homologous to spectrin and may form homodimers or oligomers. Dystrophin links two intricate systems linking the sarcolemma to the basal lamina. The COOH-terminus of dystrophin is associated with the sarcoglycans, dystroglycans, dystrobrevin, syncoilin, nNOS, and the syntrophins. The NH₂-terminus links actin, vinculin, and the integrins with laminin and the basal lamina. These two adhesion systems provide a supportive substructure to maintain the integrity of the sarcolemma. The annexins and dysferlin have a role in muscle regeneration.

ATP during contraction is essential for the maintenance of activity. ADP formed by the hydrolysis of ATP is rephosphorylated by transfer of a phosphate group from creatine phosphate (20 mM in a resting cell) by creatine phosphokinase located within the M line of the sarcomere, in the myoplasm, and between the inner and outer membranes of the mitochondria. Adenylate kinase, known in muscle as *myokinase*, catalyzes the transfer of a phosphate group between two ADP molecules, forming ATP and adenosine monophosphate (AMP). The by-products of the rapid enzymatic reactions that maintain ATP concentration are therefore creatine, P_i, and AMP. Some of the AMP is converted to inosine monophosphate by adenylate deaminase. A creatine phosphate shuttle has been proposed to enhance energy flux.⁵¹ According to this hypothesis, creatine phosphate is split within the contractile apparatus and creatine is predominantly rephosphorylated in the mitochondria.

Glycolysis

Muscles use some combination of glucose and fatty acids (and ketone bodies in some situations) as fuel, depending on their metabolic state (fasted vs. fed) and activity status (rested vs. exercise). The muscle compartment contains most of the body storage of glycogen, which is converted to glucose-6-phosphate for local use. Muscle fibers lack glucose-6-phosphatase and thus do not export glucose. During intense activity, especially in anaerobic conditions, the rate of glycolysis and the production of pyruvate exceed the rate of pyruvate consumption by the citric acid cycle. Excess pyruvate is reduced to lactate by lactate

dehydrogenase, which has tissue-specific isoforms. The lactate-dehydrogenase reaction also produces nicotinamide adenine dinucleotide (NAD⁺), which is necessary for glycolysis, but otherwise lactate is not useful within the muscle. Lactate is freely permeable through the sarcolemma, and a local increase in the extracellular lactate concentration or acidification produces exertional pain ("the burn"). Lactate is transported through the blood to the liver, where it is converted back to pyruvate and then to glucose, which is released into the blood for use by other tissues, such as muscle and brain. This sequence of steps, termed *the Cori cycle*, transfers some of the high metabolic load to the liver and "buys time" until oxidative metabolism is available.

Oxidative Phosphorylation

In aerobic conditions, pyruvate enters the mitochondria, where it is converted to acetyl-coenzyme A (CoA). Acetyl-CoA can enter the tricarboxylic acid cycle, where it is oxidized to CO₂ and H₂O, generating reduced NAD (NADH). Fatty acids also contribute to the mitochondrial acetyl-CoA pool through the process of beta-oxidation. The reducing equivalents NADH and FADH₂ are subsequently oxidized by the electron transport chain, and an H⁺ gradient is established across the mitochondrial membrane. This gradient is used to catalyze the phosphorylation of ADP to ATP by the mitochondrial ATP synthase. When glycolysis and oxidative phosphorylation are combined, for example, up to 38 ATP molecules can be generated by the oxidation of each molecule of glucose. This process is energetically much more favorable than the production of lactate, but it can

Table 5-3 Classification of Muscular Dystrophies

Disease	Genetic Locus	Inheritance	Protein	Outcome
Duchenne/Becker		XR	Dystrophin	Lethal
Emery-Dreifuss		XR	Emerin, lamins A and C	40% lethality
Limb-Girdle Muscular Dystrophies				
LGMD 1A	5q31	AD	Myotilin	With LGMD, less-severe forms can emerge during the first three decades, leading to loss of ambulation after 30 yr of age. The most severe forms start at 3-5 yr of age and progress rapidly.
LGMD 1B	1q11-q21	AD	Laminin A/C	
LGMD 1C	3p35	AD	Caveolin	
LGMD 1D	6q23	AD	—	
LGMD 1E	7q	AD	—	
LGMD 1F	7q32	AD	—	
LGMD 1G	4p21	AD	—	
LGMD 2A	15q15.1-q21.1	AR	Calpain 3	
LGMD 2B	2p13	AR	Dysferlin	
LGMD 2C	13q12	AR	γ-Sarcoglycan	
LGMD 2D	17q12-q21.33	AR	α-Sarcoglycan	
LGMD 2E	4q12	AR	β-Sarcoglycan	
LGMD 2F	5q33-q34	AR	δ-Sarcoglycan	
LGMD 2G	17q11-q12	AR	Telethonin	
LGMD 2H	9q31-q34.1	AR	E3-Ubiquitin ligase (TRIM32)	
LGMD 2I	19q13.3	AR	Fukutin-related protein	
LGMD 2J	2q24.3	AR	Titin	
LGMD 2K	9q34	AR	Protein O-mannosyltransferase	
CMDs with CNS Involvement				
Fukuyama CMD	9q31	AR	Fukutin	LE, 11-16 yr
Walker-Warburg CMD	1p32	AR	O-Mannosyltransferase	LE, <3 yr
Muscle-eye-brain CMD	1p32-34	AR	O-MNAGAT	LE, 10-30 yr
CMDs without CNS Involvement				
Merosin-deficient classic type	6q2	AR	Merosin (laminin A ₂)	Many patients never walk; others have an LGMD pattern
Merosin-positive classic type	4p16.3	AR	Selenoprotein N1, collagen VI α ₂	Course stabilizes in late childhood; many continue to walk into adulthood
Integrin-deficient CMD	12q13	AR	Integrin α7	Presents early in infancy with hypotonia and delayed milestones
Other Dystrophies				
Facioscapulohumeral	4q35	AD	—	20% wheelchair bound
Oculopharyngeal	14q11.2-q13	AD/AR	Polyadenylate binding protein nuclear 1	Onset: ≈48 yr, 100% symptomatic by age 70
Myotonic dystrophy	19q13.3	AD	DMPK, CCHC-type zinc finger and CNBP	Onset: 50% show signs by age 20; variable severity

AD, autosomal dominant; AR, autosomal recessive; CCHC, cysteine and histidine amino acid sequence in this class of zinc finger; CMD, congenital muscular dystrophy; CNBP, cellular nucleic acid-binding protein; CNS, central nervous system; DMPK, dystrophin myotonia-protein kinase; LE, life expectancy; LGMD, limb-girdle muscular dystrophy; O-MNAGAT, O-mannose β -1,2-N-acetylglucosaminyl transferase; XR, X chromosome related.

occur only when molecular oxygen is available. Myoglobin is an iron-heme complex protein that facilitates oxygen transport within muscle cells. Tissue hydrostatic pressure in a contracting muscle often exceeds arterial perfusion pressure, so the strongest contractions are anaerobic. The content of oxidative enzymes, myoglobin, and mitochondria determines the predominant type of energy metabolism and varies in different muscle types, as was discussed previously (see Table 5-2).

FATIGUE AND RECOVERY

During intense or prolonged activity, muscle fatigue is caused by alterations of metabolite levels that suppress force generation at the contractile apparatus, during excitation-contraction coupling, or both.⁵² Markedly increased

myoplasmic P_i and H^+ concentrations and decreased creatine phosphate levels have been detected by magnetic resonance spectroscopy.⁵³ When the creatine phosphate level declines, maintained activity depends on glycogenolysis until glycogen stores are depleted. During prolonged intense activity, the respiratory and circulatory systems are unable to meet the oxygen demands of the tissue. Force production declines well before the ATP concentration is compromised.

The chemomechanical link between P_i release and force generation (see Figure 5-4) implies that increased myoplasmic P_i in fatigued muscle reduces the magnitude of force simply by mass action.⁴⁰ Decreased pH in the muscle, caused in part by lactate accumulation, and insufficient availability of acetylcholine at the neuromuscular junction, leading to failure of synaptic transmission, also contribute

to decreased work production. Because the respiratory and circulatory systems do not supply sufficient oxygen to support metabolism during intense activity, an oxygen debt is incurred. Blood flow and oxygen uptake continue at an enhanced level after the period of exercise to reclaim this energy. Rephosphorylation of creatine can take place within a few minutes, but glycogen resynthesis requires several hours. Recovery processes also involve restoration of ionic gradients across membrane-bound compartments and require consumption of further energy.

PLASTICITY

The strength and endurance of a muscle are altered dramatically within weeks after changes in the demands for its use, its mobility, or its hormonal or metabolic environment. The effects of this adaptive response should be considered in any clinical situation that causes a substantial shift in these factors and with regard to the long-term life quality of the patient.

Adaptation to Muscle Use/Disuse

Muscle is a use-dependent tissue, meaning that its functional characteristics are closely tied to the number and type of activity patterns that it experiences. Increased muscle use through physical exercise leads to adaptations in muscle fibers that include alterations in specific contractile, regulatory, structural, and metabolic proteins, as well as changes in neural recruitment patterns. The type (aerobic vs. resistance), frequency, intensity, and duration of a training stimulus and the external load influence the adaptive response.⁵⁴ Resistance training causes cross-sectional hypertrophy of primarily fast type II fibers (see Table 5-2) by increasing the size of existing fibers without inducing hyperplasia. This hypertrophy is driven primarily by increased myofibrillar protein, which occupies the vast majority of fiber volume ($\approx 80\%$), but other myocellular components (e.g., mitochondria) are also increased so as to maintain the relative volume fraction of each cellular component constant with hypertrophy. Aerobic training, on the other hand, enhances the oxidative capacity and volume density of mitochondria in oxidative type I and IIA fibers, and generally does not induce hypertrophy. In this context, resistance training can be seen as altering function by increasing the overall quantity of the muscle, whereas aerobic training alters the functional quality of the muscle to elicit greater endurance to repetitive contraction.

When physical activity is reduced, for instance with bed rest during hospitalization, the cross-section of the fibers decreases, which causes muscle weakness, and endurance is reduced. Of note, these changes are worsened when accompanied by acute and chronic disease,⁵⁵ to the extent that up to 10% of muscle protein content can be lost per week.⁵⁶ After significant periods of muscle disuse, loss of muscle strength and endurance can progress to the point where patients are unable to accomplish simple activities of daily living. Although younger, healthy individuals tend to regain muscle size and function readily with exercise rehabilitation, the extent to which older individuals and those with chronic disease can recover from muscle disuse appears to be impaired.

Hormonal Control

Hormones, acting in an endocrine or paracrine-autocrine fashion, also have the capacity to alter muscle structure and function. The most prominent hormonal controller of muscle is insulin, which regulates muscle anabolism in response to feeding by suppressing protein breakdown and facilitating protein synthesis via stimulation of amino acid uptake into muscle. In addition to insulin, insulin-like growth factor-I (IGF-I), which largely mediates the effects of growth hormone on muscle, stimulates the hypertrophy of existing muscle fibers by stimulating muscle protein synthesis and inhibiting protein breakdown, and may contribute to muscle growth/regeneration through effects on muscle satellite cells.^{57,58} In men, testosterone has clear anabolic effects on muscle, and conditions that reduce circulating testosterone levels lead to muscle atrophy and weakness. The role of testosterone in women is less certain. Estrogen in women is widely believed to have effects on muscle size and strength, although experimental evidence to support this contention is lacking, and the effects of estrogen on other metabolic processes in muscle appear to be relatively minor at concentrations observed during normal menstrual cycles and in the postmenopausal period.

In many acute and chronic illnesses, changes in the hormonal milieu can affect muscle. The most predominant factors thought to elicit these changes are cytokines and other inflammatory modulators,⁵⁹ although alterations in classic stress hormones, such as cortisol and glucagon,⁶⁰ also contribute to muscle catabolism. In most cases, the effect of these catabolic hormones is to direct amino acid substrates toward the liver to necessarily support the acute phase protein response. In addition, the type of persistent low-grade inflammation that occurs with aging and in many chronic diseases may have similar detrimental effects on muscle when compounded over extended periods of time. Whether modulation of these catabolic hormonal factors has beneficial effects in maintaining muscle size and functionality under physiologic and pathophysiologic conditions, however, is not certain.

AGING

Sarcopenia, defined as loss of skeletal muscle mass and function with age, manifests as an inability to perform simple tasks of everyday life and contributes to disability, a greater risk for falls and fractures, an increase in all-cause mortality, and, in general, a poor quality of life. Normal individuals exhibit an approximately 30% decrease in total muscle mass between the ages of 30 and 80. Although it is universally accepted that whole muscle force production is reduced with age,⁶¹⁻⁶⁴ there is disagreement about whether this is due solely to reduction in muscle mass, or if loss of force production per unit muscle size is also a factor. Most single fiber studies that have measured isometric force production per unit fiber cross-sectional area (i.e., this accounts for age-related reductions in muscle size) show that aging decreases force-producing capabilities.⁶⁵⁻⁷² In addition, whole muscle^{61,62,73-75} and single fiber^{65,67-69,71,72,76} studies typically find decreases in contractile velocity with age, and this leads to further reduction in the muscle performance of the elderly, especially for movements requiring high-velocity

contractions. Altogether, these results suggest that aging alters the fundamental contractile properties of skeletal muscle fibers, which decrease, at least in part, whole muscle performance. Age-related changes in motor unit recruitment, activation of agonist and antagonist muscles, and fibrosis can exacerbate single fiber changes and further reduce whole muscle performance.

SUMMARY

The complex functional capacity of muscle to produce finely tuned and coordinated movements is ultimately expressed as the transduction of chemical to mechanical energy by actomyosin. A twitch is initiated by an action potential propagated from the central nervous system along an α -motoneuron, neuromuscular chemical transmission, direct protein-protein communication at the T-tubule-sarcoplasmic reticulum junction, Ca^{2+} diffusion in the myoplasm, and Ca^{2+} binding to thin filament regulatory proteins. Because the central nervous system controls activity through recruitment of motor units, gradation and coordination of movement depend critically on the pattern of connections between α -motoneurons and muscle fibers and on variations of properties among motor units. Development, maintenance, and aging of the muscular system involve a complex series of genetic programs and cellular interactions that are beginning to be understood at the molecular level. Adaptation of motor unit properties is evident not only in training regimens but also in reduced activity caused by pain or joint immobilization and in compromised metabolic, hormonal, or nutritional conditions. Hence, the plasticity of muscle influences the clinical course of many diseases. In addition to its importance in pathophysiology, muscle serves as an excellent substrate for understanding the molecular basis of cell development, protein structure-function relationships, cell signaling, and energy transduction processes.

KEY POINTS

Kinematics is the study of the geometric and time-dependent aspects of motion without analyzing the forces causing the motion.

The general unconstrained movement in three-dimensional space requires the description of three translations and three rotations to fully describe joint motion.

Kinetics is the study of the forces that cause motion of a rigid body. These forces can be classified as either external forces or internal forces.

External forces represent the action of objects contacting the body, gravitational forces, or force due to inertia of the body.

Internal forces are the body's responses to external forces, which consist of muscle, ligament, and joint contact forces.

Due to the relatively smaller mechanical advantages, large muscle and tendon forces and thus the internal joint forces are expected when performing any activities.

The anatomic structure responsible for joint constraint can be divided into passive and active elements. Passive elements, consisting of the capsulo-ligamentous structures and bony articulating surfaces, provide static constraints of the joint. The active elements include muscle-tendon units, which provide dynamic constraints of the joint.

Biomechanics combines the field of engineering mechanics with the fields of biology and physiology. Biomechanics applies mechanical principles to the human body. Knowledge of biomechanics is essential in order to understand the intricate interrelationship between mechanical and non-mechanical influences on the musculoskeletal system. An understanding of the loads and properties of the musculoskeletal system is necessary in order to understand the mechanical influences on bone and joint health. Forces that load the joints are generated by muscles and transmitted by tendons. Bones must withstand these forces. Developments in the field of biomechanics have improved our understanding of normal and pathologic gait, mechanics of neuromuscular control, and mechanics of growth and form. This knowledge has contributed to the development of medical diagnostic and treatment procedures. It has provided the basis for designing and manufacturing medical implants, orthotic devices, and rehabilitation therapy. Biomechanics has also been used for improving human performance in the workplace and in athletic competition.

Mechanics is a branch of physics that is concerned with the motion and deformation of bodies that are acted on by mechanical forces. Mechanics is one of the oldest physical sciences dating back to Aristotle (384-322 BC) with his organized analysis of animal movement. Leonardo daVinci (1452-1519) worked on the mechanics of the human body, and his detailed anatomic sketches represent the birth of anatomy as a discipline and mechanics as the science governing human motion. Although daVinci wrote extensively on body mechanics, the man generally credited to be the father of modern biomechanics is Giovanni Alphonso Borelli (1608-1679). His book *De motu Animalian* provided a quantitative graphical solution to a musculoskeletal biomechanics problem (Figure 6-1).¹

Engineering mechanics is the discipline devoted to the solution of mechanical problems through the integrated application of mathematic, scientific, and engineering principles. With roots in physics and mathematics, engineering mechanics is the basis of all engineering mechanical sciences. Engineering mechanics is an applied mechanics branch of the physical sciences. The broad field of applied mechanics can be further divided into three main parts: rigid body mechanics, deformable body mechanics, and fluid mechanics. In general, a material can be characterized as either a solid or fluid. Solid materials can then be considered to be rigid or deformable. A rigid body is one that cannot be deformed. In reality, every object undergoes deformation to some extent when acted on by external forces. However, this is a definition of convenience that is used to simplify complex problems. For example, during the study of movement in gait analysis, the bones are considered to be rigid bodies when compared with the soft tissues joining the bones. External loads applied to a rigid body result in internal loads, stresses, and deformations. The mechanics of deformable bodies deals with the relationships between externally applied loads and their internal effects. The mechanics of deformable bodies has strong ties with the field of materials science and is more complex as compared with the analyses required in rigid body mechanics. The purpose of this chapter is to give you only a brief idea of biomechanics. Our focus is on rigid body mechanics.

Basic biomechanics relies heavily on Newtonian mechanics. These laws were introduced by Sir Isaac Newton and form the basis for analyses in statics and dynamics. Statics analyzes the forces that occur in rigid bodies that are in static equilibrium. Dynamics is the study of bodies in motion. The general field of dynamics consists of two major areas: kinematics and kinetics. Ultimately, proper joint constraint and stability enable the function of limbs in characteristic ways.

Figure 6-1 Borelli's quantitative graphical solution to a musculoskeletal biomechanics problem. (From Borelli GA: *De motu animalium*, Batavis, 1685, Lugduni.)

KINEMATICS

Kinematics is the study of the geometric and time-dependent aspects of motion without analyzing the forces causing the motion. Kinematic analysis is used to relate displacement, velocity, acceleration, and time. To study kinematics in an organized manner, it is common to classify the motion as translational, rotational, or general. Translational motion occurs when a straight line drawn between two points on the body remains in the same direction during the motion. Translational motion can be either rectilinear motion (if the paths are straight lines) or curvilinear (if the paths are curved lines). Rotational motion occurs when the points on the body move in a circular path around an axis of rotation. The angular motion occurs about a central line known as the *axis of rotation*, which lies perpendicular to the plane of motion. The third class of motion is called *general motion*, or *displacement*, which occurs if a body undergoes both translational and rotational motion simultaneously.

Kinematics can be analyzed in two-dimensional (2-D) or three-dimensional (3-D) space. When all points of a rigid body move parallel to a plane, the motion is referred to as *planar motion*. This motion can be thought of as 2-D motion. 3-D motion is the more general type of rigid body motion. This motion requires six independent parameters to describe the general type of motion. These parameters are called "degrees of freedom" or the number of independent coordinates in a coordinate system that is required to completely specify the position of an object in space. A rigid body in space has a maximum of six degrees of freedom: three translations (expressed by linear coordinates) and three rotations

(expressed by angular coordinates). The general movement of an object is defined by a vector quantity that is a combination of both linear and angular displacement. Velocity is the time-related change of displacement. Linear velocity is expressed in units of length per time (m/sec). Angular velocity is expressed in units of angular measure per time (rad/sec). Because velocities reflect vector quantities, both magnitude and direction must be specified. Acceleration is the time rate of change of velocity. Linear acceleration is expressed in units of length per time squared (m/sec^2). Angular acceleration is the time rate of change in angular velocity (rad/sec^2). Accelerations are also vector quantities, and both magnitude and direction must be specified.

Kinematic techniques have been used to study body movements in both 2-D and 3-D space. The human body is typically modeled as a number of interconnected rigid body segments (Figure 6-2). A coordinate system is affixed to each rigid body segment in order to establish an anatomic coordinate system. External markers are used to define orthogonal coordinate systems whose axes define the position of these body segments. Joint motion is then described as the relative motion of the distal body segment with respect to the proximal body segment. Limb segments are assumed to undergo angular displacement during human movement. However, more sophisticated analyses will also quantify the linear displacement that limb segments may undergo. These measures of relative segmental angles have been used to describe human walking and other activities of daily living.²⁻⁷

As an example, knee motion in the sagittal plane can be characterized throughout the gait cycle (Figure 6-3). At

Figure 6-2 Body-fixed reflective markers used for establishing anatomic coordinate systems. **A**, Video camera measurement systems calculate the location of external markers placed on the body segments and aligned with specific bony landmarks. **B**, A body-fixed external coordinate system is then computed from three or more markers on each body segment. Body-fixed external coordinate systems are shown for the thigh, T_r , and shank, S_r . The coordinate system is shown for the three orthogonal directions (e.g., x , y , z). So, the body-fixed thigh coordinate system is designated T_{Tx} , T_{Ty} , and T_{Tz} . **C**, Using a subject-specific calibration converts the external coordinate system to an anatomic coordinate system through the identification of anatomic landmarks (e.g., the medial and lateral femoral condyles and medial lateral malleoli). The anatomical coordinate system for the thigh is then designated T_{Ax} , T_{Ay} , and T_{Az} . (Reproduced from Kaufman KR: *Objective assessment of posture and gait*. In Bronstein AM, Brandt T, Marjorie H, editors: *Clinical disorders of balance, posture, and gait*, Oxford, England, 2004, A Hodder Arnold Publication.)

heel strike, the knee is nearly fully extended (knee flexion of 5 degrees). During midstance, the knee flexes to about 15 degrees, which occurs at 15% of the gait cycle. The knee joint is brought back into extension by midstance. At 50% of the gait cycle, opposite foot contact occurs. The weight is shifted to the opposite limb, and the knee begins flexing. Toe-off occurs at 60% of the gait cycle. Peak knee flexion of 60 degrees occurs during the swing phase. The knee motion can be described as two flexion waves, each starting in relative extension, progressing into flexion, then returning again to extension. The first flexion wave, or stance phase knee flexion, acts as a shock absorber to aid weight acceptance. This curve peaks in early stance at opposite foot-off. The mechanical source for this shock absorber is the eccentrically contracting quadriceps muscles. The second flexion wave is necessary in order to clear the foot in early swing phase. The knee is rapidly flexed beginning

just after heel rise to a maximum in swing phase just as the swinging foot passes the opposite limb.

The complexity of kinematic analysis increases substantially when going from planar analysis to 3-D analysis. The complexity of the analysis arises from the technical difficulty that large rigid body rotations cannot be treated as vectors and, hence, do not obey the vectorial principles of transformation, independence, and interchangeability of operations. For finite spatial rotation, the sequence of rotations is extremely important and must be specified for a unique description of joint motion.^{8,9} For the same amount of rotation, different final orientations will result from different sequences of rotation (Figure 6-4). However, with proper selection and definition of the axes of rotation between two bony segments, it is possible to make finite rotation sequence independent or commutative.^{8,9} The concept of Eulerian angles has been adopted in the field of orthopedic biomechanics to unify the definition of finite spatial rotation. In the selection of reference axes, one axis is fixed to the stationary segment and another axis is fixed to the moving segment (Figure 6-5). In the knee joint, for example, the flexion/extension angle, Φ , occurs about a medial-laterally directed axis defined by a line connecting the medial and lateral femoral condyles. The axial rotation angle, ψ , is measured about an axis defined by the line along the shaft of the tibia. The third axis, also defined as the floating axis, is orthogonal to the other two axes and defines abduction/adduction, Θ . These rotations match the Eulerian angle description and are thought to be performed in such a way as to bring the moving segment from the reference orientation into the current orientation. The advantage of using this system for description of the spatial rotation of anatomic joints is that the angular rotations do not have to be referred back to the neutral position of the joint because the rotation sequence can be independent.

Figure 6-3 Knee sagittal plane motion throughout the gait cycle. A positive value indicates knee flexion. For the first 60% of the gait cycle, the leg is in stance. The leg is in swing phase for the remainder of the gait cycle.

Figure 6-4 This example illustrates the sequence dependence of rigid body motion. The object undergoes two rotations about the X-axis and Z-axis. The sequence of these rotations differs in the top and bottom rows. The result is that the final orientation of the object is different.

Thus the measurement can be easily obtained and related to anatomic structures.

A complete analysis of total joint movement (i.e., six degrees of freedom) can be obtained using markers embedded in the bone^{10,11} or dual fluoroscopic imaging techniques.^{12,13} This general unconstrained movement in 3-D space requires the description of three translations and three rotations to fully describe joint motion. The most commonly used analytic method for description of six degrees-of-freedom displacement of a rigid body is the screw displacement axis (SDA).¹⁴⁻¹⁶

Figure 6-5 Description of knee joint motion using Eulerian angle system. An axis, e_ϕ , fixed to the distal femur defines flexion/extension motion, ϕ . An axis, e_ψ , fixed to the proximal tibia along its anatomic axis defines internal external rotation, ψ . A floating axis, e_θ , orthogonal to the other two axes is used to measure abduction-adduction, θ . The rotation matrix, $[T]$, between the proximal and distal joint segment is then given by the multiplication of the three rotation matrices associated with the rotations around the three axes (i.e., $[T] = [T_\psi][T_\theta][T_\phi]$). (Reproduced with permission from Chao EYS: Justification of triaxial goniometer for the measurement of joint rotation, J Biomech 13:989-1006, 1980.)

KINETICS

Kinetics is the study of the forces that cause motion of a rigid body. When there are unbalanced forces or moments acting on a rigid body, it is under a nonequilibrium, or dynamic, condition, resulting in motion. Understanding the kinetics of human movement provides a fundamental understanding of the musculoskeletal system. Before one can begin to analyze the forces during human movement, some basic definitions and assumptions must be made.

The key quantities in kinetics are force, moment, and torque. Forces represent an interaction between two bodies. Forces can be contact forces (bodies touching each other) or field forces (bodies separated by a distance, such as gravitational, electric, or magnetic forces). Forces are represented by vectors. Vectors are composed of four components: magnitude, direction, sense, and position (also called *point of application*). According to Newton's Second Law, force is any action that tends to change the state of rest or state of motion of a body to which it is applied. Forces are represented by vectors. The vector may be resolved into several component forces, usually along specified mutually perpendicular coordinate axes. Conversely, forces can be summed using vectorial addition. A moment represents the turning, twisting, or rotational effect of a force. A moment is a vector. A moment is defined as the product of the force and the perpendicular distance between the line of action of the force and the axis of rotation of the motion that the force produces (Figure 6-6). Its magnitude is the force times the perpendicular distance to the axis of rotation. The direction of the moment is along the axis of rotation (or potential rotation) and thus perpendicular to the plane in which the twisting force is applied. The moment arm, the distance used to calculate the moment, is the shortest distance from the force action line to the actual or potential pivot point of the system, regardless of the state of motion. Skeletal

Figure 6-6 The moment (M) of a force (E) about a point is equal to the force times the moment arm (d), which is the perpendicular distance between the point and the line of action of the force. The moment arm may (A) or may not (B) be the distance along the limb segment to the axis of rotation. The moment arm is always the shortest distance between the line of force application and the axis of rotation.

motions are the result of moments applied by muscles that cross the joints on which they act. Moments of a force about an axis measure the tendency of the force to impart to the body a motion of rotation about a fixed axis. A torque is a special type of moment that results when a pair of forces that have equal magnitude, parallel lines of action, and opposite senses act on a body (Figure 6-7). The magnitude of the torque is Fd , where d is the perpendicular distance between the two forces. The resultant force is zero because the two forces are equal and oppose each other.

Kinetics can be used to analyze forces affecting the musculoskeletal system. These forces can be classified as either external or internal. External forces represent the action of objects contacting the body, gravitational forces, or force due to inertia of the body. Internal forces are the body's

Figure 6-7 A torque, or force couple, is created by two equal, noncollinear, parallel but oppositely directed forces F and $-F$. The magnitude of the torque is Fd , where d is the perpendicular distance between the two forces.

responses to external forces. Internal forces consist of muscle, ligament, and joint contact forces. In general, the limb segments are assumed to be rigid. This simplifies the analysis because the structure is assumed to not deform under load. Further, joints are assumed to be frictionless hinges.

Statics is the study of forces acting on a body at rest. When performing a force analysis, the body or part of a body at equilibrium may be isolated from the environment and the environment is replaced by forces acting on the system. This is called a free-body diagram. Because both forces and moments are vectors, they must sum to zero in each of the three perpendicular directions (reference system). Consider a person standing quietly (Figure 6-8). The person's weight (force of gravity) tends to pull the person toward the ground (Figure 6-8A). The person does not move downward because the ground is pushing up with a total force equal in magnitude to the individual's weight (Newton's Third Law). If the person has his or her weight distributed symmetrically, then their weight is evenly shared by each lower extremity (see Figure 6-8A). The load under each foot can be represented by resultant ground reaction force (GRF) vectors with one half of the body weight supported by each foot. With one half of body weight supported by each foot, the point of application of the resultant GRF passes approximately midway between the subject's two feet (Figure 6-8B). There is no motion because the external forces (i.e., body weight and GRF) are balanced—they are equal and opposite in magnitude. When the person leans to one side (Figure 6-8C), the GRF shifts in the direction that the person leans. Thus overall body posture can affect the GRF location. If the person leans more, he or she will become unstable (i.e., the downward body weight vector will fall outside the base of support). In order to remain in static equilibrium, the subject requires additional support (Figure 6-8D). The horizontal force applied to the upper body by the wall is balanced with an equal and opposite horizontal GRF component. Also, the two equal and opposite vertical forces are no longer aligned (i.e., collinear). They form a force couple that would tend to rotate the body in a counterclockwise direction. A second clockwise force couple formed by the two equal and opposite horizontal forces balances the counterclockwise force couple. As a result, the subject remains in both translational and rotational static equilibrium.

When there are unbalanced forces or no one is acting on a rigid body, it is under a nonequilibrium, or dynamic, condition resulting in motion. Newton's Second Law of Motion links the kinematics of a body to its kinetics. The Second Law states, "If the resultant force acting on a body is not zero, the body will have an acceleration proportional to the magnitude of the resultant and in the direction of this resultant force." Analysis of the motion of the limb segments requires a set of governing equations and assumptions. The equations assume that each limb segment is a rigid body moving in 3-D space. Therefore six scalar equations of motion define the general 3-D forces and motion of each limb segment:

$$\sum F = ma$$

$$\sum M = I\alpha$$

Figure 6-8 Static force equilibrium. **A**, When the person stands quietly with the body weight evenly distributed on both feet, the person can be considered in static equilibrium. **B**, The loads under each foot can be combined into a single ground reaction force (GRF) equal to the sum of the forces under the two feet and located directly under the center of mass (COM) with a force equal to body weight. The GRF is located approximately midway between the two feet. **C**, As body weight is shifted laterally, the GRF also shifts in order to remain under the COM. **D**, When the body weight vector is shifted beyond the base of support (i.e., the lateral margin of the foot), an additional lateral force vector is required to maintain static equilibrium. (Reproduced from Davis RB, Kaufman KR: *Kinetics of normal walking*. In Rose J, Gamble JG, editors: *Human walking*, ed 3, Philadelphia, 2006, Lippincott Williams & Wilkins.)

where ΣF is the sum of forces in each of three orthogonal directions, ΣM is the sum of moments, I is the moment of inertia of the body, a is the linear acceleration of the body, m is the mass of the body, and α is the angular acceleration of the body. Newton's Second Law makes it possible to calculate the forces acting on the musculoskeletal systems from measurements of segment motion and mass. During normal ambulation, there is a medial and vertical GRF that balances the body weight and lateral inertial force. The vertical GRF component generally passes lateral to the body's center of mass (COM) during gait (Figure 6-9A). The combined resultant GRF passes medial to the knee joint center, creating a load imbalance in the medial and lateral compartments of the knee. The medial and lateral compartment of the knee carries more load than the lateral compartment of the knee (Figure 6-9B). Thus the medial compartment typically develops more osteoarthritis than the lateral compartment. The resultant GRF vector creates a knee external adduction moment. Medial tibiofemoral OA is the most common, and it has become apparent that medial knee OA is at least partially mechanically driven. The peak external knee adduction moment has been implicated in the progression of radiographic OA¹⁷ and has been identified as a marker of disease severity.^{18,19}

JOINT BIOMECHANICS

Diarthrodial joints connect long bones to allow force transmission and joint rotation. The type of joint articulating

motion depends on the shape of the joint surfaces. For example, the hip is a congruent ball-and-socket joint, the elbow is a congruent hinge joint, the knee and proximal interphalangeal joints are bicondylar joints, and the carpometacarpal joint of the thumb is a saddle joint. In general, the joint articulating motion can be described in terms of sliding, spinning, and rolling (Figure 6-10). Both sliding and spinning motions involve the relative translation of one surface against the other. Rolling has the least relative motion between articulating surfaces. The translational speeds range from 0.06 m/s between the femoral head surface and acetabular surface during normal walking to 0.6 m/s between the humeral head surface and glenoid surface during baseball pitching.²⁰

Although diarthrodial joints experience an enormous amount of loading and motion, the cartilage surfaces undergo little wear and tear during normal conditions. This is due to the special lubrication qualities of synovial fluid and the biphasic structure of the cartilage. Synovial fluid, secreted by the synovium into the joint space, contains mainly hyaluronate. Biomechanically, hyaluronate is a highly viscous liquid in which the shear stress depends on the rate of shear strain applied. As the shear rate increases, the viscosity of synovial fluid decreases. However, in the rheumatoid patient, due to enzymatic degradation of the hyaluronate molecules, the viscosity of the rheumatoid synovial fluid does not have a normal shear rate dependency and is believed to be less effective in lubrication.²⁰

Figure 6-9 Schematic of a person in single support during gait. **A**, External demand. The body weight and vertical ground reaction force (GRF) couple tend to rotate the body clockwise. The medial shear GRF and the corresponding lateral inertial force produce a force-couple that tends to rotate the body counter-clockwise. Thus the body is in dynamic equilibrium. **B**, Internal response. The resultant GRF passes medial to the knee joint, creating an external knee adduction moment. The external moment is balanced internally in the knee by creating a larger force on the medial tibial plateau (*M*) than on the lateral tibial plateau (*L*). Once again, the knee is in dynamic equilibrium.

Figure 6-10 The motions of joint articulation: spinning, rolling, and sliding. (From Morrey BF, Itoi E, An KN: *Biomechanics of the shoulder*. In Rockwood CA, Matsen F, editors: *The shoulder*, ed 2, vol 1, Philadelphia, 1998, WB Saunders, pp 233–276.)

Figure 6-11 Hydrodynamic lubrication. Surfaces moving relative to each other have an interposed viscous fluid that increases the pressure within the fluid to support the weight and keep the two surfaces separated. (From Mow VC, Soslowsky LJ: *Friction, lubrication, and wear of diarthrodial joints*. In Mow VC, Hayes WC, editors: *Basic orthopaedic biomechanics*, New York, 1991, Raven Press, pp 245–292.)

Two lubrication mechanisms in the synovial joint provide minimal friction and cartilage wear: fluid film lubrication and boundary lubrication. During joint rotation, the sliding speed of the articulating surfaces and the viscosity of the synovial fluid create a thin film, which is capable of supporting the load, resulting in fluid film lubrication. When the joint is loaded, the two articulating surfaces approach each other and a squeeze film is generated to support the load. The pressure developed in the lubricating fluid carries the load applied to the joint. The thin film of lubricant also produces a greater bearing surface. In addition, the cartilage is a biphasic porous medium. Water is bounded in the intrafibrillar space of the collagen matrix by proteoglycans. Intricate interaction of the mechanical stress, the electric charges, and the hydrodynamics results in a special fluid efflux pattern known as *elastohydrodynamic lubrication* (Figure 6-11). The fluid exudation ahead and imbibition behind the moving contact point of the articulating surface further facilitates the lubricant film.²⁰

On occasion, heavy loading exceeds the capacity that the lubricant film can support. In this situation, the cartilage surfaces are in direct contact. Under this condition, lubrication is provided by the mechanism of boundary lubrication.²⁰ Boundary lubrication is accomplished by a monolayer of glycoprotein called *lubricin*, a superficial zone protein. In the pathologic condition of osteoarthritis, the structure properties of cartilage such as porosity and permeability are altered. The fluid efflux and the synovial fluid film are diminished, and boundary lubrication is the remaining mechanism of joint lubrication.

JOINT CONSTRAINT AND STABILITY

The human body can perform complex motions because the joints allow multiple degrees of freedom between articulating bones. Due to the variations in anatomic structures of the joints, various limbs have different movement characteristics and load transmissions. Adequate joint stability that balances motion and loads is necessary for a joint to

function properly. Chronic disease or traumatic injury may cause damage to joint tissue, thus compromising the joint constraints and stability. To improve the diagnosis and treatment of such joint disorders, it is essential to understand the basic mechanics of the constraint, which provides stability. The anatomic structure responsible for joint constraint can be divided into passive and active elements. Passive elements, consisting of the capsulo-ligamentous structures and bony articulating surfaces, provide static constraints of the joint. The active elements include muscle-tendon units, which provide dynamic constraints of the joint.

The contribution of capsulo-ligamentous structures to joint stability and constraint is determined by the change in length, the line of action, and the material properties of the tissue (Figure 6-12). For a given loading and displacement of the joint, the greater the elongation of the soft tissue, the higher the passive tension generated by that tissue. However, the specific contribution of such passive tension to joint constraint further depends in turn on the relative line of action of the capsulo-ligament structures. Therefore the relative locations of the origins and insertions of the ligaments may determine the contribution of the ligamentous tension in resisting joint displacement in three orthogonal directions. Surgical alterations of the soft tissue

Figure 6-12 With the joint loaded or displaced, the capsulo-ligamentous tissues are stretched and thus the passive tensions are developed. The amount of tension developed depends on the amount of deformation, as well as the material properties of the soft tissue. The location of the capsulo-ligamentous attachment on the bone and the direction of bony movement regulate not only the amount of deformation but also the direction of passive tension in stabilizing the joint.

attachment to the bone would therefore change the constraints of the joint.

The lengthening and shortening of the capsulo-ligamentous structures during joint loading and movement determine the deformation of the tissue. The material properties of the tissue along with the amount of the deformation will determine the passive tension of the structure. For the same amount of deformation, the stiffer the tissue, the higher the tension will be; the softer the tissue, the lower the tension. Alterations of the material properties due to physiologic and pathologic conditions will definitely alter the joint constraint and the articulation. For example, the tight posterior capsules of the baseball pitcher would limit the range of physiologic motion. On the other hand, the softening of capsulo-ligamentous structures during pregnancy and in rheumatologic diseases could all potentially lead to abnormal motion and contact stress on the joint surface. These alterations of the soft tissue material properties must be considered as essential factors in initiating the early degeneration of joint cartilage and may lead to the vicious cycle of arthritis.

Experimentally, the significance of various passive anatomic structures to joint stability has been assessed using two methods; the stiffness test and the laxity test. The stiffness test is commonly used to determine the relative contributions of individual anatomic elements to joint constraint. The laxity test is considered to demonstrate the outcome of joint instability when one or more constraining units are compromised. In the stiffness test, the joint is displaced under controlled testing and the corresponding load is monitored. On the basis of the joint load-displacement curves, it is obvious that the load required to displace the joint is higher when all the ligaments are intact than when a ligament is lacerated. The difference in the constraining load between these two curves at the same joint displacement represents the contribution to the joint constraint of that particular sectioned ligament. Because the capsulo-ligamentous structures are passive tissues, as long as the joint displacement is controlled and experimentally reproduced, the relative contributions of individual tissues will not be dependent on the sectioning sequence of soft tissue. Contrary to the stiffness test, in which displacement is varied and load measured, in the laxity test, a specific load is applied to the joint and the extent of joint displacement is measured. Joint laxity is documented with changes in displacement as anatomic elements are removed. The joint laxity as observed and measured would provide more of a clinical scenario in that joint instability would be experienced by the patient who has encountered a similar soft tissue injury.

In addition to the soft tissue constraints, the joint articulating surface is another element in providing joint constraint and stability. Theoretically, its significance to joint stability is determined by both the geometric shapes of the joint surfaces and the amount of compressive force encountered between those two surfaces (Figure 6-13A). When two curved surfaces articulate, a vertically applied force will induce either a transverse displacement or a transverse constraining force. The greater the congruency between the curved articulating surfaces, the greater the induced lateral joint constraint force. This mechanism is sometimes referred to as *concavity-compression*. In the shoulder joint, for

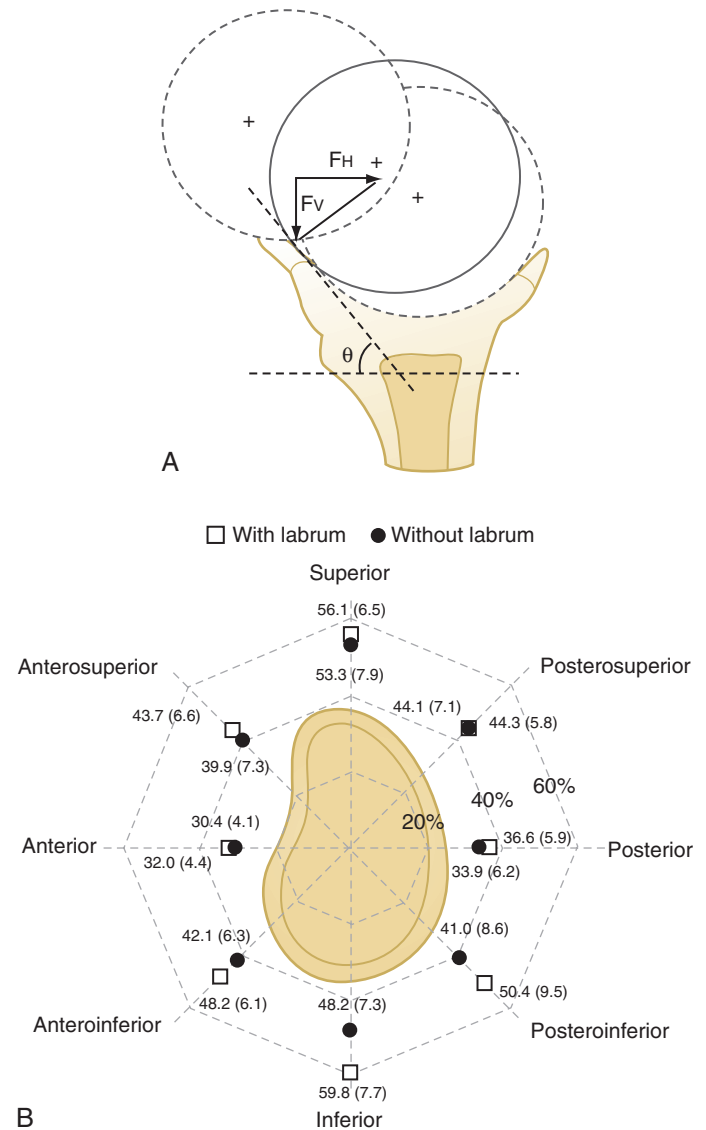

Figure 6-13 **A**, Transverse displacement of bone in the curved joint requires elevation against the articulating surfaces. With compressive F_v applied, any transverse movement will encounter a resistance, F_h . If either the mating joint surface is flat, for example, $\theta = 0$, a compressive force, or F_v is not available, there will be no transverse constraint, $F_h = 0$. **B**, The stability ratio, defined as transverse constraint force F_h divided by the applied compressive force F_v , was measured. This measure indicates the stability through the joint-surface interaction, independent of the magnitude of the compressive force applied.

example, the relative translations between the glenoid and the humeral head and the forces resisting translation were recorded. The stability ratio, defined as the peak translational force divided by the applied compressive force, was higher in the hanging-arm position than in glenohumeral abduction (Figure 6-13B). The highest stability ratio was detected in the inferior and superior directions. The anterior direction was associated with the lowest stability ratio. Resection of the glenoid labrum resulted in an average decrease in the stability ratio of 10%. In the treatment of traumatic recurrent anterior shoulder instability, patients with a large osseous glenoid defect are at risk for recurrent instability after arthroscopic Bankart repair. Bone-grafting performed in shoulders with a large osseous glenoid defect

to restore the articulating surface provides excellent clinical outcomes.

In order to benefit for joint constraint through the concavity-compression, the compressive or oppositional force across the joint surface is required. This joint compressive force is usually generated by the muscle contraction forces. The relative location and direction of the resultant joint force to the available articulating surfaces will determine the potential stability of the joint. For example, in the glenohumeral joint, if the resultant force is well located at the center of the glenoid articulating surface, the joint is considered stable. When the resultant force is directed outside the available joint surfaces, joint dislocation is most likely. However, when the resultant force is located within the joint surfaces but more toward the rim of the glenoid surface, there is potential for subluxation of the joint. The interaction of muscle force resulting in the resultant joint constraint forces is illustrated later.

Intra-articular or intra-capsular pressure is the other component of the passive and static constraint of the joint (Figure 6-14). The joint is usually surrounded by a capsule and sealed with synovial tissue. When the capsule is intact, any distraction force stretches and deforms the capsulo-ligamentous structure and will generate negative intra-articular pressure. This negative intra-articular pressure will counteract further displacement. When the joint capsule is vented, such negative pressure can no longer develop and cannot constrain the joint. The negative intracapsular pressure is there for the constraint of all joints. However, it is especially important for those joints under gravitational distraction such as the shoulder joint.

Active muscle contraction is important for joint stability. Proper coordination of muscle contraction could provide dynamic joint constraint. On the other hand, deficiency of muscle innervation or defect of tendon could result in unfavorable joint constraint and lead to joint instability. That is, the muscle force can act not only as a joint stabilizer but possibly a joint dislocator as well. The contribution of muscle/joint constraint is similar to that of passive capsulo-ligamentous tension, theoretically determined by the line of action along the passive and active tension of the muscle. Based on the relative position of the bony structure and the direction of the joint displacement, the same muscle-tendon

structure can contribute differently to joint constraint. When the joint is spanned by multiple muscles, the coordination of muscle contraction would ultimately determine the dynamic stability of the joint. For example, the line of action of the muscle was measured and the contributions of muscle contractions to the articulating surfaces of the shoulder were described in the normal and shear directions (Figure 6-15). The shear component has direct influence on the transverse translation of the bony element at the joint. In contrast, the normal component of the muscle force provides the compressive force to bring the surfaces together. A glenohumeral joint with a lax capsule and loose ligaments might be dynamically stabilized if the glenoid concavity is maintained and the function of the external and internal rotators, efficient stabilizers in the position, is enhanced. On the other hand, in the patient with rotator cuff tear, the pull of the major movers such as deltoids during arm elevation of forward rotation will result in the resultant joint force into the superior and anterior directions, and superior impingement and anterior instability are thus expected.

In general, muscle contraction will generate moments about all three axes of rotation of a given joint. However, when the constraints from other periarticular soft tissues are not available, the muscle will be primarily responsible for maintaining the balance of the joint's rotation. If a muscle crosses multiple joints, the recruitment of muscle activities depends on the moments of all the joints it spans. The concept of muscle with multiple joints is of extreme clinical importance. For example, when considering rehabilitation after reconstructive surgery of the anterior cruciate ligament, the goal is to strengthen the muscles without excessive tension being placed on the ligament. Quadriceps loading, especially with the knee in a near extended position, would result in anterior joint shear force and displacement of the tibia. Such shear force would induce tension in the anterior cruciate ligament. The concept of kinetic-chain has been used extensively to address this problem. In fact, the principle is simply based on two-joint muscles. During closed-kinetic-chain type exercises such as the squat and the leg press, the foot is fixed and motion at the knee is accompanied by motion at the hip and ankle joints. The GRF causes flexion moments at both the knee and the hip joints. The antagonistic muscle of hamstrings at the knee

Figure 6-14 Effect of negative intra-articular pressure on shoulder joint stability. In the normal situation, traction on the arm causes an increase in negative intra-articular pressure and joint distraction is constrained. On the contrary, if the capsule is vented and air or fluid is introduced into the joint, traction on the arm no longer affects the intra-articular pressure, but instead, the joint will be subluxed inferiorly.

Figure 6-15 Coordination of the muscle contractions to accomplish a given task can be well demonstrated by the situation that the deltoid and rotator cuff muscles work together to elevate the shoulder joint. **A**, For patients with rotator cuff tear, the shoulder elevation will be accomplished by the deltoid muscle alone. The resultant joint force would be directed superiorly due to the line of action of the deltoid muscle. Under this situation the joint is not stable; therefore superior subluxation and migration would be expected. **B**, On the other hand, when elevating the shoulder with the rotator cuff muscle alone, the direction joint resultant force would point toward the center of the glenoid surface, which would make the joint stable. However, the magnitude of the joint resultant forces is relatively high, which may not be ideal for the cartilage tissue. **C**, Ideally, shoulder elevation is accomplished with the combination of the deltoid muscles as the workhorse to provide the strength and power, along with the rotator cuff muscles as the sterling in directing the joint resultant force to keep the joint in a more stable condition.

joint is thus recruited to balance the hip flexion moment. Co-contraction of quadriceps and hamstrings at the knee joint reduces the anterior joint shear force and the tension in the anterior cruciate ligament.²¹

KEY POINTS

An understanding of the mechanisms of postnatal tissue repair provides potential therapeutic targets to enhance intrinsic tissue regeneration.

Because tissue repair mimics the cellular and molecular cascade of embryonic tissue formation, it is anticipated that investigating the role of developmental pathways in joint and skeletal disorders/diseases will identify novel therapeutic targets.

Cellular therapeutics and their related products are complex with regard to mechanism of action and manufacture; this has evolved as a concept into advanced therapy medicinal products (ATMPs) with a specific regulatory path.

Recent advances in regenerative medicine and tissue engineering relevant to rheumatology have entered clinical practice and include the repair of joint surface defects by autologous chondrocyte implantation and bone repair using adult mesenchymal stem cells.

Tissue engineering is adopting the concept of biomimetics of in vivo tissue development. Developmental engineering is the term used to describe this novel method for the rational and accurate design of robust, well-controlled manufacturing processes of "biological spare parts."

With dramatic advances in targeted treatments for arthritic disease, inflammation can be kept under control quite efficiently. In addition, a better understanding of the destructive processes beyond inflammation in arthritic disease has identified new molecular targets, such as metalloproteinases, and cellular targets, such as the osteoclasts. These findings in turn have led to the development of new treatment approaches that effectively contribute to improved control of the destruction of joint and joint-associated tissues. The new challenge in arthritic disease is to position all these therapeutic opportunities properly, ultimately leading to a stratified approach (i.e., giving optimal treatment to the proper patient at the right time). New principles have emerged in the management of arthritic disease, such as early detection, remission induction and maintenance therapy, tight disease control, patients at risk and responders to treatment; these have become a part of daily clinical practice.¹⁻³

These developments and in particular the widespread use of new biologics such as tumor necrosis factor (TNF) inhibitors have highlighted the need to consider other aspects of joint biology, in particular the mechanisms driving tissue response and repair.⁴ Indeed, to restore the balance between

Regenerative Medicine and Tissue Engineering

FRANK P. LUYTEN

tissue destruction and tissue repair (Figure 7-1), we should be looking arguably at the overview picture (i.e., the "systems biology" of the joint). Introducing regenerative medicine provides a novel opportunity to restore joint homeostasis, thus possibly leading to cure. Targeting repair has entered our discipline, and investigating the potential to activate and enhance joint tissue repair mechanisms has become a prime goal.

Regenerative medicine, encompassing tissue engineering, seeks to repair or regenerate damaged tissues and organs, regardless of the cause of the insult, without leaving scar tissue behind, thereby restoring both structure and function of tissues/organs. Nature demonstrates that this is achievable because successful wound healing and fracture repair typically are processes that happen routinely in the postnatal individual, even until advanced age. Indeed in many patients, it is not possible to detect after the healing process where the skin wound or fractured bone site was. We also know, as demonstrated in fetal surgery, that this scarless repair is partially age and context dependent. Thus it is attractive to envision that with an improved and in-depth understanding of repair processes at the cellular and the molecular level, we may be able to interfere quickly at the time of injury to guide the healing process appropriately, thereby preventing scar formation. Postnatal tissue healing mimics the developmental processes of tissue formation.

As an example of, and of relevance for, skeletal tissues, it appears that the process of rebuilding an adult limb has many similarities with how the limb is formed a priori in the embryo; signaling mechanisms are required to specify the final pattern. Thus limb formation and limb regeneration are likely to employ similar molecular pathways.⁵ Remarkable advances in developmental biology over past decades have provided the knowledge platform to advance into novel regenerative medicine approaches in postnatal life. These advances include not only improved understanding of the mechanisms of body axis formation and organogenesis, but also impressive progress in stem cell biology, including the regulation of stemness and stem cell niches, lineage specification and cell differentiation, and the critical molecular pathways involved.

In view of this, we are now in a position to enter a new era in regenerative medicine and tissue engineering.^{6,7} In this chapter, we will briefly review approaches seeking to repair damaged and diseased tissues, in particular diarthrodial joints and skeletal structures.

When we seek to repair tissues, two mechanistic approaches are possible: (1) enhancing intrinsic repair mechanisms through stimulation of cell proliferation, differentiation, and tissue metabolic activity, while recruiting endogenous progenitor populations into the damaged tissue;

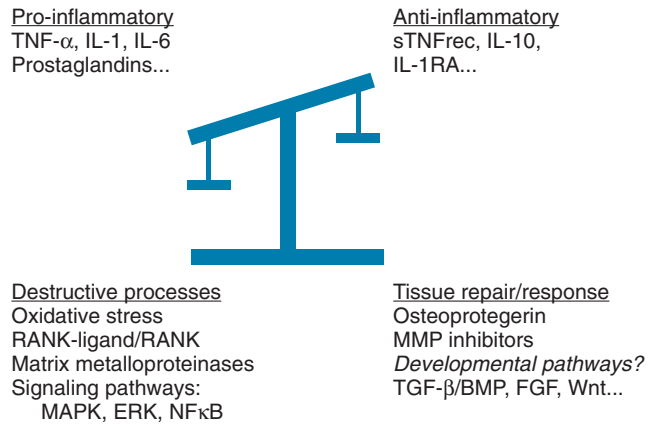

Figure 7-1 “Systems biology” view of chronic arthritis. The severity and outcome of disease are determined by the balance between inflammation/destructive processes and anti-inflammatory signals with repair attempts. BMP, bone morphogenetic protein; ERK, extracellular receptor kinase; FGF, fibroblast growth factor; IL, interleukin; IL-1RA, interleukin-1 receptor antagonist; MAPK, mitogen-activated protein kinase; NFκB, nuclear factor kappa B; RANK, receptor activator of nuclear factor kappa B; sTNFrec, soluble tumor necrosis factor receptor; TGF-β, transforming growth factor-beta; TNF-α, tumor necrosis factor-alpha.

and (2) if insufficient intrinsic repair leads to clinical symptoms and signs, with loss of function, extrinsic repair needs to be considered (i.e., tissue engineering approaches generating cell populations and combination products that can contribute mostly locally to tissue repair processes). We will now discuss these approaches in greater depth.

INTRINSIC TISSUE REPAIR

As the body strives to maintain homeostasis of postnatal tissues and thus undergoes continuous tissue remodeling, many signals counteract destructive processes in tissues. Disease processes may allow destructive processes to become dominant, leading to loss of tissue homeostasis and loss of function. Enhancement of expression/secretion of signals counteracting the breakdown processes is a straightforward approach to restore homeostasis. Naturally occurring examples include production of soluble receptors or receptor antagonists (sTNF receptors, interleukin [IL]-1RA), use of inhibitors of matrix modeling enzymes such as tissue inhibitors of metalloproteinases (TIMPs), and inhibition of osteoclast formation caused by blocking the receptor activator of nuclear factor κB (NFκB) (RANK)/RANK ligand (RANKL)/osteoprotegerin (OPG) system. Some of these targets have reached the clinic; others are in early or late phase clinical trials across a range of diseases, including rheumatoid arthritis (RA), psoriatic arthritis (PsA), and osteoarthritis (OA). Note, however, that in some arthritic diseases such as ankylosing spondylitis, the tissue response is abnormal, leading to joint ankylosis (for review, see Lories et al⁸).

Because postnatal tissue repair mimics in many aspects tissue formation during development, strong arguments have been put forth for the belief that *developmental pathways* involved in formation of the joint and joint-associated tissues may be interesting targets for enhancing tissue repair.

Typical developmental pathways critically involved in the formation of skeletal tissues and structures such as the synovial joints are contained in the transforming growth factor (TGF)-β superfamily, including bone morphogenetic proteins (BMPs) and growth differentiation factors (GDFs), the Wnt family of proteins, fibroblast growth factors (FGFs), the hedgehog (Hh) proteins, parathyroid hormone (PTH)/PTH-related protein (PTHrP), and notch signaling. It is not the intention of this chapter to discuss in detail these pathways, but rather to select a few examples of how these signaling pathways are involved in joint formation and to discuss their role in postnatal joint repair. Specific focus is placed on some of those pathways that have led to advances in early clinical development of arthritic disease.

TGF-β/BMP Signaling

Recent reviews have highlighted the relevance and critical role of members of the TGF-β superfamily (TGF-β, BMPs, GDFs) in the biology of articular cartilage, bone, joints, and joint-associated tissues, during development, in postnatal tissue homeostasis and repair, and in tissue response on injury and aging. TGF-β has been shown to be involved in the maintenance and aging of articular cartilage and in osteoarthritis.⁹ BMPs have been reported to play major roles in articular cartilage metabolism, with BMP7/OP1 being of particular interest.^{10,11} In addition, data indicate that modulation of TGF-β/BMP downstream receptor-Smad signaling plays an essential role in both the regulation of chondrocyte differentiation and the development and progression of osteoarthritis.¹² It is therefore not surprising that because of overwhelming evidence of the regenerative potential of this family of growth and differentiation factors in preclinical models, their therapeutic potential is being explored. In particular, several ongoing phase I studies on osteoarthritis of the knee are seeking to target OP1/BMP7 (clinicaltrials.gov). In addition, a search is ongoing, through peptide technology (peptidomimetics) or small molecule screens, to identify modulators of the TGF-β/BMP receptor-Smad signaling pathways.¹³ Because the nature of the synovial joint allows for local treatment, it is expected that some of the newly identified compounds will first be tested in local application such as joint surface repair. Indeed because this family of proteins, in particular the BMPs, plays a role in many systemic processes, BMP technology may be required to focus in the first place on local treatment, as exemplified in the use of BMP devices already in the clinic for orthopedic applications such as spine fusion and healing of non-union.^{14,15} Wider systemic morbidity upon targeting BMP pathways is as yet unclear.

FGF Signaling

Extensive investigations have identified FGFR3 signaling as a key regulator of chondrocyte and osteoblast function both during development and postnatally. In particular, absence of signaling through FGFR3 in the joints of *Fgfr3*^{-/-} mice leads to premature cartilage degeneration and early arthritis.¹⁶ These degenerative changes were accompanied by increased expression of MMP13 and type X collagen, cellular hypertrophy, and loss of proteoglycan at the articular surface. One of the key ligands of FGFR3 signaling appears

to be FGF18 (for review, see Haque et al¹⁷). In the postnatal joint, FGF18 has significant anabolic effects on cartilage metabolism. The efficacy of FGF18 was tested in a rat meniscal tear model of OA.¹⁸ Intra-articular injection of FGF18 induced a dose-dependent increase in cartilage formation and a reduction in cartilage degeneration scores in the medial tibial plateau of OA rats. It is important to note that this effect was seen only in OA joints, not in normal rat joints, suggesting that this effect may be a specific response to tissue injury. It is interesting to note that at the molecular level, this joint protective effect may be due in part to its interaction with other signaling pathways such as BMP signaling by repressing noggin, a BMP antagonist.¹⁹ These findings, combined with enhanced understanding of FGF18 signaling in postnatal cartilage and bone biology, led to the development of local treatment with FGF18 and the design of early-phase clinical trials (clinicaltrials.gov) in patients with cartilage lesions and in those with OA of the knee.

Wnt Signaling

Recent findings indicate a critical role for Wnt signaling in cartilage and bone biology, with specific relevance to osteoporosis and osteoarthritis (for review, see Luyten et al²⁰). Most available data provide circumstantial and/or direct evidence, both in vivo and in vitro, that activation of Wnt/ β -catenin signaling leads to reprogramming of articular chondrocytes toward catabolism or loss of their stable phenotype, with subsequent loss of articular cartilage tissue structure and function. *Frzb*^{-/-} mice lacking this Wnt antagonist show increased activity of the Wnt signaling pathway, leading to increased bone stiffness and enhanced cartilage damage.²¹ It is important to note that upon induction of joint changes reminiscent of OA by enzymatic treatment (papain-induced osteoarthritis), by accelerated instability (collagenase-induced ligament and meniscal damage), or by inflammation (methylated bovine serum albumin [mBSA]-induced monoarthritis), *Frzb*^{-/-} mice showed greater cartilage loss than their wild-type counterparts.²² Increased cartilage damage in *Frzb*^{-/-} mice was associated with higher levels of β -catenin-dependent Wnt signaling and with higher expression levels of matrix metalloproteinase 3. It was also demonstrated that FRZB can inhibit directly matrix metalloproteinase 3, probably through the netrin domain, indicating the potential complexity of the underlying mechanisms of observed phenomena. The role of Wnt signaling as a key regulatory pathway in postnatal joint biology and joint remodeling in chronic arthritis was further highlighted by the findings of Diarra and co-workers.²³ Through inhibition of DKK1, an antagonist of the canonical Wnt signaling pathway, in a transgenic mouse model of TNF-driven inflammatory arthritis, part of the bone destructive effect was reversed. In view of the complexity of Wnt signaling and its potential downstream effects, it is important to further study the specific roles of canonical and noncanonical Wnt signaling in cartilage, bone, and the osteochondral junction, allowing Wnt-activated pathways and their components to become separate targets for therapeutic intervention. In view of this, recent findings of specific upregulation of Wnt16 in postinjury joint cartilage and in

OA are of interest and open the opportunity for joint-specific Wnt targeting.²⁴

Other Potential Anabolic Treatments

Other targets besides skeletal developmental pathways are signaling molecules that play a critical role in postnatal joint tissue homeostasis and turnover. These proteins/pathways can be regarded as potential postnatal *anabolic* agents contributing to the restoration of joint homeostasis. In this regard, the growth hormone (GH)/insulin-like growth factor (IGF) axis appears to be of interest. In particular, IGF-I has been reported to be critical in the maintenance of homeostasis of articular cartilage explants *ex vivo*.²⁵ Further evidence of its anabolic effect in *in vivo* models has led to the early clinical development of intra-articular treatments with IGF-I in gonarthrosis, although no recent reports of ongoing clinical trials have been found. Alternatively, successful local delivery via gene therapy has been reported.²⁶

Furthermore, it was reported that systemic administration of GH in horses may be beneficial for joint/articular cartilage biology, as it increases IGF-I levels in synovial fluid.²⁷ Improved formulations of GH have been explored to improve duration and effect size in synovial joints.²⁸

A relationship between levels of IGF-I and osteoarthritis has been suggested, further suggesting a potential benefit of targeting the GH/IGF-I axis, particularly in OA. However, data so far are not conclusive, and further systematic analysis of the hypothalamic-pituitary axis, including growth hormone, IGF-I, and somatostatin, is required.²⁹ Taken together, the potential of GH/IGF-I as anabolic factors for joint repair and in particular their beneficial effects on articular cartilage metabolism have been recognized for a long time, but data supporting their clinical use and impact on joint biology in patients remain to be further explored.

EXTRINSIC REPAIR

Cell-based therapies and tissue engineering are starting to enter the clinical arena, and thus are becoming of relevance to clinicians today. Many preclinical and early clinical applications appear promising, including the use of embryonic (ES), induced (iPS), or adult stem cells (MSC) in neurologic, cardiovascular, and musculoskeletal tissue repair and regeneration.

The mechanisms through which cellular therapies and combination products contribute to tissue repair are multiple and involve direct engraftment, proliferation, and differentiation to tissue-specific cell types, but they also include paracrine actions such as secretion of growth and differentiation factors that enhance the local tissue response. Indeed, cellular products typically function as multisignal delivery systems and interact with the microenvironment.³⁰ In addition, it appears that adult stem cells display immunomodulatory properties; this has been clinically explored in graft-versus-host disease (GVHD) and in autoimmune diseases such as RA and systemic sclerosis. In view of this, cellular products are now subject to regulatory approval before they enter clinical practice; they belong

to the new class of advanced therapy medicinal products in Europe (ATMP; see European Medicines Agency, www.ema.europa.eu).

We herein shall discuss some applications that have reached the clinic that aim to restore the integrity and function of the locomotor system. Among them and most prominent are treatments for the repair of articular cartilage and bone defects.

Joint Resurfacing

Autologous Chondrocyte Transplantation

Regeneration or repair of symptomatic articular cartilage defects has been at the forefront of regenerative medicine ever since Brittberg and associates reported in 1994 a remarkably good clinical and structural outcome using a procedure called *autologous chondrocyte transplantation/implantation* (ACI).³¹ Briefly, cell populations were prepared by enzymatic release from a biopsy of articular cartilage taken from an unloaded area in the symptomatic joint. The chondrocytes were subsequently expanded in vitro and after six to eight population doublings were reimplanted in the joint surface defect under a periosteal flap, taken from the tibia of the same patient. This was followed by a long rehabilitation to reach optimal outcome at 18 to 24 months. This high-profile publication attracted quite some interest and triggered a wave of basic, translational, and clinical research in the field. It also evolved quickly in 1997 in the marketing of Carticel, an autologous cell product for the repair of symptomatic condylar defects of the knee, by the Genzyme Corporation in the United States.

Since that time, some progress has been made in studies aiming to improve and standardize the autologous chondrocyte preparation, the development of other delivery systems for chondrocytes, and replacement of the periosteal flap by a membrane of diverse composition. Most clinical studies were open label in design with diverse outcomes emerging (for review, see Van Osch et al³²). The study by Knutsen and colleagues, the first multicenter prospective randomized study, failed to show ACI to be superior to microfracture, a technique mostly considered as the standard of care for small (measuring less than 2 to 3 cm²) symptomatic joint surface defects.³³ Microfracture, a bone marrow stimulation procedure, is based on puncturing of the subchondral bone plate into the bone marrow, the generation of a blood clot containing precursor cell populations derived from subchondral bone marrow, and spontaneous transformation of the repair clot into a fibrocartilaginous repair tissue.³⁴ Microfracture is clearly associated with clinical benefit and with filling of the joint surface defect with repair tissue, but it is generally accepted that this repair is not durable, resulting in a consistent decline in clinical outcome over the long term. It is the aim of ACI to repair the cartilage defect with high-quality tissue matching the characteristics of neighboring tissue, resulting in improved long-term outcomes (Figure 7-2). Five-year follow-up data from this Scandinavian study did not indicate the clinical superiority of ACI over microfracture, although some indications suggest that good structural repair was associated with durable clinical outcome.³⁵

Figure 7-2 Graph reflecting expected differences between repair of a joint surface lesion by a mechanism of scarring versus true tissue regeneration. Both treatment approaches (i.e., microfracture and autologous chondrocyte transplantation [ACI]) show clinically equal short-term benefit with repair tissue closer to native tissue for a regenerative approach (e.g., as seen in ACI). Long-term outcomes are more durable with regenerative approaches, in some cases leading to cure.

In Europe, an autologous chondrocyte cell product called *ChondroCelect* emerged as the first cellular product with central registration by the European Medicines Agency (EMA) under the new ATMP regulation. In a prospective randomized multicenter study, *ChondroCelect*, defined and characterized as a cell population capable of making ectopic stable cartilage in vivo, was shown to result in structurally superior repair tissue at 12 months after implantation as compared with microfracture.³⁶ At 36 months, a strong tendency toward clinically superior outcome was noted,³⁷ and at 5 years, it was confirmed (Van Lauwe, Saris et al, abstracts, ICRS 2010, personal communication).

Although still open for debate with respect to long-term clinical durability, the consensus is that ACI can be considered a regenerative treatment with good structural and clinical outcomes. It is important to note that the data show outcomes superior to standard care if “appropriate” patients are treated. Positive predictors of good outcome include early intervention (less than 3 years of symptoms), good quality of chondrocytes, well-trained surgeons, adherence to rehabilitation protocols, and no signs of osteoarthritis (as defined by Kellgren II). Cost-effectiveness will certainly improve if the treatment is shown to prevent progression toward OA, but these data are not yet available.

Long-term clinical outcomes have been reported and indicate good durability of the treatment in a substantial number of patients over periods exceeding 10 years.³⁸

Additional Developments

The next wave of developments is related to the use of autologous and/or allogeneic progenitor cell populations for the repair of joint surface defects. Adult bone marrow stromal cells, also called *mesenchymal stem cells* (MSCs), are lead candidates for their use in the repair of cartilage defects and other skeletal tissue such as bone defects.³⁹ Other tissue sources have been explored for preparation of MSC

populations, including adipose tissue, synovium, and periosteum.⁴⁰⁻⁴² Promising data using synovially derived progenitors have been reported in vivo, but it is unclear at this point what the long-term outcomes of these approaches will be.^{43,44} In particular, the safety and durability of an allogeneic approach are not known. Prerequisites for successful outcomes include improved understanding of differentiation protocols toward the proper stable phenotype and short- and long-term immune tolerance of allogeneic cells. Also, longer-term studies will provide necessary insight into the value of these innovative treatment approaches. Finally, a better understanding of the natural course of joint surface defects is needed, as is knowledge of what predisposes toward clinical deterioration and patients at risk; as indicated previously, additional insight is needed into factors contributing to successful repair such as the proper microenvironment in the joint.

Bone Regeneration

The most promising means of fully optimizing regenerative medicine approaches in musculoskeletal medicine is bone regeneration. Bone already has a remarkable potential to heal postnatally; this indicates that all necessary tools are available in principle in the postnatal individual to obtain full tissue repair, with no tissue scarring, and thus also to achieve tissue integration and remodeling. It is critical now to understand how nature heals bone fractures postnatally and subsequently for optimal mimicking of these repair processes when bone healing goes wrong, as in delayed union and nonunion, or in the repair of large bone defects such as avascular necrosis, or after resection of bone tumor.

The standard of care in the field is the use of autologous bone grafts, typically obtained from the iliac crest. However, important developments that have moved the boundaries in the field of bone engineering include development and improvement of biomaterials and new technologies in the design and production/manufacturing of these new biomaterials. The spectrum of “smart” biomaterials for bone engineering is vast, and recent progress has resulted in the production of resorbable osteoconductive surfaces; some even display osteoinductive properties (for review, see Mieszkawska and Kaplan⁴⁵). These last characteristics in particular have been attained by coating biomaterials with bioactive factors, including growth factors such as bone morphogenetic proteins.¹⁵ BMP devices not only have led to more robust and predictable outcomes in spine fusion, but have demonstrated that recapitulation of embryonic tissue formation processes can lead to successful bone healing.

Despite all this progress, there is still considerable unmet medical need for bone healing. Indeed, we still are not able to heal larger bone defects. In view of this, we and others believe that a combined implant incorporating progenitor cell populations will be required (for a recent review, see Gómez-Barrena et al⁴⁶). Failure of bone healing typically is associated with lack of vascularization and lack of availability of proper precursor cell populations. Therefore the generation of tissue-engineered viable implants will need to come to full fruition to reach this goal. So far, the results of so-called combination products (scaffold and cells, eventually enriched with growth factors) have been somewhat

disappointing. Lack of an underlying scientific basis for the design and manufacture of these implants is probably responsible for a large part of this. Therefore a biomimetic model called *developmental engineering* was proposed and extensively described.^{47,48} A few publications have indicated that this approach indeed may be more successful than the traditional cells-on-scaffold approach.⁴⁹

REGENERATIVE MEDICINE IN ARTHRITIS

As we start to understand intrinsic tissue response mechanisms and attempts to counteract destructive processes by enhancing tissue repair, new therapeutic targets have been identified and targeted with “classical” pharmaceutical approaches such as the development of protein therapies and small molecules interfering with critical repair mechanisms.

However, these approaches still may be far from sufficient; therefore more comprehensive approaches may be required. Increasingly, cellular therapies and combination products have been explored. Indeed, cellular therapies will affect local processes in many ways as cell populations can be manufactured so that they deliver a vast array of secreted signals, also called their *secretome*, which may influence local disease processes. Conversely, it becomes clear that the microenvironment will affect cellular products and will influence what they secrete and how they interact with the environment, including their engraftment, proliferation, differentiation, and tissue integration and remodeling.⁵⁰ Therefore if regenerative medicine and cellular therapies are to be successful, particularly in disease, we need to be able to assess and quantify the microenvironment and their mutual interactions. This translates into the clinic as identifying patient responders, which points toward the importance of personalized medicine. Indeed for regenerative medicine approaches to become cost-effective and successful, identification of the patient at risk and predicting responders to treatment will be of utmost importance.

Different cellular therapeutic approaches have been investigated in chronic arthropathies; most available data relate to the use of adult MSCs. Principles have been established for distinct indications. For inflammatory diseases such as RA and other autoimmune systemic diseases, immune suppressive and immune modulatory effects of cellular therapies can contribute to control of disease activity.⁵¹ Cellular therapies to enhance tissue repair have been explored extensively in preclinical animal models of post-traumatic osteoarthritis.⁵² It has also become evident that the use and role of MSCs in particular have been explored in OA and studied intensively.^{53,54} The mechanisms through which they can influence disease processes in OA appear diverse, as already discussed, and include so-called trophic effects and immune suppressive and anti-inflammatory effects, with cell engraftment contributing to local *de novo* tissue formation leading to meniscal and cartilage repair.^{55,56} Because cellular therapies can address all these aspects, it is anticipated that properly manufactured cell products optimized for these positive effects may have a major impact when restoration of joint homeostasis is envisioned—a clinical goal that is probably crucial for interfering with disease progression in OA.

Future Directions

Regenerative medicine approaches, including enhancing and guiding intrinsic repair mechanisms, cellular therapeutics, and tissue engineering, are revolutionizing medicine in general and the field of musculoskeletal disorders and diseases in particular. We as rheumatologists will be witnessing and applying in the near future innovative regenerative and repair treatment approaches, including but not limited to repair of damaged joint surfaces, regeneration of difficult to heal fractured bones, repair of damaged ligamentous structures, and fabrication of a variety of “off the shelf” skeletal tissue structures (also called *provisional tissues* or *tissue intermediates*), such as *viable* pieces of bones, ligaments, menisci, and other joint tissues. These regenerative treatments will be of use for post-traumatic damaged joints and skeletal tissues and for (post) inflammatory and osteoarthritic joints.

Ultimately, and if everything else fails at some point leading to total organ failure (joint decompensation for the rheumatologist), implantation of a *biological* prosthesis with the potential of full tissue integration and remodeling is the dream, and proofs of principle exist to suggest that this may be within reach.^{57,58} To achieve this in a more robust and predictable fashion, we need to employ a developmental

engineering approach.^{47,48} We proposed the term *developmental engineering* to describe a method for rational and accurate design of robust, well-controlled manufacturing processes. This method integrates concepts from rapid advances in developmental biology, systems biology, and network science and is based on the design of in vitro processes consisting of sequential subprocesses corresponding to in vivo developmental stages under the control of signal pathway networks that can be modeled mathematically. They follow a gradual and coordinated progression of tissue growth and cell differentiation that leads to organization of cells into intermediate tissue forms with modular behavior. The macroscopic developmental modularity of tissues can be attributed to a corresponding modularity of network topology that describes gene interactions during the developmental process. We propose that identification of gene network modules that control developmental modules in vivo is the central theoretical and practical problem of both tissue engineering and developmental biology. Close interaction between the efforts of biologists and those of engineers can speed up tissue engineering processes.

Connection to the Clinic

1. Regenerative treatments and tissue engineering approaches should aim for beneficial long-term outcomes with cure as the ultimate goal.
2. New therapeutics, including growth and differentiation factors targeting intrinsic repair, are in early stages of clinical development.
3. Cell-based therapies and combination products appear promising in the field of musculoskeletal disorders, mostly in posttraumatic indications, and some tissue engineering approaches have reached the clinics.
4. Autologous chondrocyte implantation appears to result in long-term benefit for patients with symptomatic cartilage defects of the knee. Additional data in clinical practice are required to establish proper treatment algorithms. Similar approaches in other joints have been explored, but investigation is ongoing.

Proteinases and Matrix Degradation

YASUNORI OKADA

KEY POINTS

Proteinases are generally classified into aspartic proteinases, cysteine proteinases, serine proteinases, and metalloproteinases according to catalytic mechanism.

Because of the acidic pH optima and intracellular localization within lysosomes, most of the aspartic proteinases and cysteine proteinases are involved in intracellular degradation of extracellular matrix (ECM) components.

Serine proteinases and metalloproteinases are neutral proteinases and play a central role in extracellular degradation of ECM macromolecules.

ECM-degrading metalloproteinases are composed mainly of the MMP (matrix metalloproteinase) and ADAMTS (a disintegrin and metalloproteinase with thrombospondin motifs) gene families.

Endogenous proteinase inhibitors are proteinase class specific, whereas α_2 -macroglobulin inhibits the activities of all proteinases.

The activities of ECM-degrading proteinases at the local tissues are regulated by the balance between the proteinases and their inhibitors, which may be determined by production rates of proteinases and inhibitors, their secretion, activation of proenzymes, and anchoring systems of the activated proteinases to cell surfaces.

ProMMPs (zymogens of MMPs) are activated via the extracellular, intracellular, and pericellular pathways depending on the MMP species.

Aggrecan and type II collagen, two major ECM components, in articular cartilage may be degraded by differential or complementary actions of the MMP and ADAMTS species in arthritides.

In rheumatoid arthritis, articular cartilage is destroyed by proteinases accumulated in synovial fluid, direct contact of proteolytic synovium and pannus tissue, and proteinases derived from chondrocytes, whereas bone is resorbed by osteoclasts mainly by the action of cathepsin K and MMP-9 under acidic and hypercalcemic conditions in subosteoclastic compartments.

In osteoarthritis, chondrocyte-derived metalloproteinases including the MMP and ADAMTS species contribute primarily to the breakdown of articular cartilage.

proteolytic turnover and remodeling of ECM are transient and highly controlled under physiologic conditions, and excessive degradation of ECM components by proteinases causes tissue destruction in many pathologic conditions. In rheumatoid arthritis and osteoarthritis, ECM-degrading proteinases are elevated without sufficient endogenous inhibitors and they are believed to play central roles in the destruction of articular cartilage and bone on the basis of a local imbalance between proteinases and inhibitors. This chapter provides up-to-date information about the ECM-degrading proteinases and their inhibitors.

EXTRACELLULAR MATRIX DEGRADING PROTEINASES

ECM is degraded by endopeptidases (i.e., proteinases) that act internally on polypeptide chains; little evidence is present for the roles of exopeptidases that cleave one or a few amino acids from the N- or C-terminus. Proteinases comprise aspartic proteinases, cysteine proteinases, serine proteinases, and metalloproteinases, which are classified according to catalytic mechanism. Proteinases from each of the four classes are involved in the degradation of ECM macromolecules.

Aspartic Proteinases

Most aspartic proteinases have two aspartic acid residues in their catalytic sites, where the nucleophile that attacks the scissile peptide bond is an activated water molecule. Mammalian aspartic proteinases include the digestive enzymes (pepsin and chymosin), the intracellular cathepsin D and cathepsin E, and rennin. Among the proteinases belonging to this group, cathepsin D is the major aspartic proteinase involved in ECM degradation (Table 8-1). It exhibits proteolytic activity against most substrates such as aggrecan and collagen telopeptides with pH optima between pH 3.5 and 5. Because of the acidic pH optima and intracellular localization within lysosomes, cathepsin D is probably responsible for intracellular degradation of phagocytosed ECM fragments that previously were degraded in the extracellular spaces. A study on cartilage explant cultures using the aspartic proteinase inhibitor suggests, however, the possibility that cathepsin D secreted extracellularly contributes to the degradation of aggrecan in articular cartilage.¹

Cysteine Proteinases

Cysteine proteinases are endopeptidases in which the nucleophile of the catalytic site is the sulfhydryl group of a cysteine residue. The ECM-degrading cysteine proteinases

Extracellular matrix (ECM) plays critical roles in normal development and function of the organism by interacting with cells and supporting tissue structures. The in vivo cellular functions regulated by cell-ECM interaction include proliferation, differentiation, apoptosis, and motility. The

Table 8-1 Proteinases That May Be Involved in Degradation of Extracellular Matrix

Enzyme	Source	Inhibitor
Aspartic Proteinases		
Cathepsin D	Lysosome	Pepstatin
Cysteine Proteinases		
Cathepsin B	Lysosome	Cystatins
Cathepsin L	Lysosome	Cystatins
Cathepsin S	Lysosome	Cystatins
Cathepsin K	Lysosome	Cystatins
Calpain	Cytosol	Calpastatin
Serine Proteinases		
Neutrophil elastase	Neutrophils	α_1 -PI
Cathepsin G	Neutrophils	α_1 -Antichymotrypsin
Proteinase 3	Neutrophils	α_1 -PI, elafin
Plasmin	Plasma	Aprotinin
Plasma kallikrein	Plasma	Aprotinin
Tissue kallikrein	Glandular tissues	Aprotinin; kallistatin
tPA	Endothelial cells; chondrocytes	PAI-1; PAI-2
uPA	Fibroblasts; chondrocytes	PAI-1; PAI-2; PN-1
Tryptase	Mast cells	Trypstatin
Chymase	Mast cells	α_1 -PI
Metalloproteinases*		
MMPs	Tissue cells; inflammatory cells	TIMP-1, 2, 3, and 4; RECK for MMP-2, 7, 9, and 14
ADAMTSs	Tissue cells	TIMP-3
ADAMs	Tissue cells; inflammatory cells	TIMP-3; RECK for ADAM10

*For details of MMPs, ADAMTSs, and ADAMs, see Tables 8-2, 8-3, and 8-4.

ADAMs, a disintegrin and metalloproteinases; ADAMTSs, a disintegrin and metalloproteinases with thrombospondin motifs; MMPs, matrix metalloproteinases; PAI, plasminogen activator inhibitor; PI, proteinase inhibitor, PN, proteinase nexin; RECK, reversion-inducing, cysteine-rich protein with Kazal motifs; TIMP, tissue inhibitor of metalloproteinases; tPA, tissue-type plasminogen activator; uPA, urokinase-type plasminogen activator.

include lysosomal cathepsins B, L, S, and K and the calpains (see Table 8-1). Cathepsins B and L digest the telopeptide regions of fibrillar collagen types I and II, the nonhelical regions of collagen types IX and XI, and aggrecan at acidic pH. Cathepsin S has a similar spectrum of substrates within a broad range of pH values. Cathepsin K, also called *cathepsin O*, *O2*, or *X*, is a collagenolytic cathepsin that efficiently cleaves type I collagen at the triple helical regions at pH values between 4.5 and 6.6.² The proteinase also degrades gelatin and osteonectin. On the basis of the data that cathepsin K is highly expressed by human osteoclasts³ and inactivating mutations or deletion of the gene result in an osteopetrotic phenotype in humans and animals, cathepsin K is believed to play a key role in bone resorption in joint diseases (see later). Because cathepsins B, L, S, and K are expressed in synovium or articular cartilage or both in rheumatoid arthritis and osteoarthritis, they may also be involved in the cartilage destruction through degradation of the ECM macromolecules.⁴

Calpains are Ca^{2+} -dependent, papain-like cysteine proteinases and are ubiquitously distributed among mammalian cells. The best-characterized members of the calpain superfamily are μ -calpain and m-calpain, which also are called

conventional (μ -calpain) and *classic* (m-calpain) *calpains*.⁵ Calpains are involved in various pathologic conditions such as muscle dystrophy by acting intracellularly. They are present in the extracellular spaces and in osteoarthritic synovial fluid, and they can degrade aggrecan.

Serine Proteinases

Serine proteinases require the hydroxyl group of a serine residue acting as the nucleophile that attacks the peptide bond. They include the largest number of proteinases classified to about 40 families. Most can degrade ECM macromolecules. The major ECM-degrading serine proteinases in joint tissues are subsequently described (see Table 8-1).

Neutrophil Elastase and Cathepsin G

Neutrophil elastase and cathepsin G are serine proteinases that are synthesized as precursors in promyelocytes in bone marrow and subsequently stored in the azurophilic granules of polymorphonuclear leukocytes as active enzymes. Mature leukocytes do not synthesize elastase, but they mobilize azurophilic granules to the cell surface and release the proteinases in response to various stimuli. Monocytes have low levels of elastase but lose the enzyme during the differentiation into macrophages. Neutrophil elastase and cathepsin G are basic glycoproteins with isoelectric points larger than 9 (neutrophil elastase) and about 12 (cathepsin G). They can be readily trapped in cartilage matrix that has a negative charge.

Neutrophil elastase and cathepsin G cleave elastin; the telopeptide region of fibrillar collagen types I, II, and III; other collagen types IV, VI, VIII, IX, X, and XI; and other ECM components such as fibronectin, laminin, and aggrecan at neutral pH. These serine proteinases also can be involved indirectly in the breakdown of ECM by activating the zymogen of matrix metalloproteinases (proMMPs)⁶ and by inactivating endogenous proteinase inhibitors such as α_2 -antiplasmin, α_1 -antichymotrypsin, and tissue inhibitors of metalloproteinases (TIMPs).

Mast Cell Chymase and Trypsin

Chymase and trypsin are packaged in secretory granules together with histamine and other mediators in mast cells, which are infiltrated in rheumatoid synovium. Chymase is a chymotrypsin-like proteinase with a broad spectrum of activity against ECM components such as type VI collagen⁷ and aggrecan. It also activates proMMPs such as proMMP-1, proMMP-3, and proMMP-9.⁶ Although prochymase is activated intracellularly and stored in the granules, the activity in the granules is limited at low pH and becomes fully active when released extracellularly. Trypsin is a trypsin-like proteinase that degrades collagen type VI⁷ and fibronectin; it also activates proMMP-3.⁶

Plasmin and Plasminogen Activators

Plasminogen is synthesized in liver and secreted to plasma. It can bind to fibrin and to cells, and after activation by plasminogen activators, plasmin readily digests fibrin. Membrane-bound plasmin also degrades many ECM

components including proteoglycan, fibronectin, type IV collagen, and laminin.⁸ Other important functions of plasmin are to initiate the activation of proMMPs,⁶ activate latent cell-associated transforming growth factor (TGF)- β 1, and act as proenzyme convertase. Plasmin is generated through activation of plasminogen mainly by plasminogen activators, principally two serine proteinases, tissue-type plasminogen activator (tPA) and urokinase-type plasminogen activator (uPA).

The tPA is synthesized as a proenzyme of 70 kD and is secreted into the circulating blood primarily by endothelial cells, fibroblasts, chondrocytes, and tumor cells.⁸ In addition to being a major activator of plasminogen for fibrinolysis, tPA plays a key role in the clearance of fibrin from the circulation.

The uPA molecule was first purified from urine as a proenzyme of 54 kD.⁸ It is converted to the active form of two chains of 30 kD and 24 kD linked by a disulfide bond. Another fully active form of 33 kD is generated by plasmin. Although the expression of uPA is limited to certain cells such as renal tubules and bladder urothelium under physiologic conditions, it is more widely expressed in various cells including invasive cancer cells, migrating keratinocytes, and activated leukocytes in pathologic situations. Pro-uPA and two-chain uPA bind to a specific uPA receptor, a single-chain glycoprotein with a glycosylphosphatidylinositol (GPI) moiety expressed on fibroblasts, macrophages, and tumor cells. Receptor-bound uPA preferentially activates cell membrane-bound plasminogen into plasmin. Cell membrane-bound plasmin can activate receptor-bound pro-uPA. Among its specificities, uPA has a limited action on fibronectin.

Kallikreins

Two types of kallikreins, plasma and tissue kallikreins, are known. Plasma kallikrein, with two disulfide-linked chains (36 kD and 52 kD), is generated from prokallikrein of 88 kD by coagulation factor XIIa or by kallikrein itself. It activates kininogens to bradykinin and activates proMMP-1 and proMMP-3.⁶ Tissue kallikrein is synthesized in glandular tissues. It releases Lys-bradykinin from kininogen and activates proMMP-8.⁶

Metalloproteinases

Similar to aspartic proteinases, metalloproteinases are endopeptidases in which the nucleophilic attack on a peptide bond is mediated by a water molecule. A divalent metal cation, usually zinc, activates the water molecule. Among the metalloproteinases, MMPs (matrix metalloproteinases), which are also designated matrixins (a subfamily of the metzincin superfamily), are key ECM-degrading, zinc-dependent endopeptidases (Table 8-2). Accumulated evidence indicates, however, that some members of the ADAMTS (a disintegrin and metalloproteinase with thrombospondin motifs) family, which is an MMP-related gene family, also are involved in the degradation of ECM, especially cartilage proteoglycan (Table 8-3). Only a few members of the ADAM (a disintegrin and metalloproteinase) family have limited activity to ECM components (Table 8-4).

Matrix Metalloproteinases

The human MMP family comprises 23 different members, which have MMP designations (numbered according to a sequential numbering system) and common names coined by the authors of the published reports (see Table 8-2). On the basis of the biochemical properties provided by the domain structures and on their substrate specificity, these family members are classified into two major subgroups: secreted-type MMPs and membrane-anchored MMPs. MMP-4, MMP-5, and MMP-6 are excluded from the list because they are identical to other known MMPs (i.e., MMP-3 and MMP-2). MMP-18 and MMP-22 also are missing in Table 8-2 because they are assigned to *Xenopus* collagenase-4 and chicken MMP.

Most secreted-type MMPs including collagenases, stromelysins, and other MMPs are composed of three basic domains—the propeptide, catalytic, and hemopexin-like domains—that are preceded by hydrophobic signal peptides (Figure 8-1). The N-terminal propeptide domain has one unpaired cysteine in the conserved sequence of PRCGXPD. The cysteine residue in the sequence interacts with the essential zinc atom in the catalytic domain to prevent it from binding the catalytic water molecule, maintaining the proenzyme in an inactive state. The catalytic domain has the zinc-binding motif HEXGHXXGXXH, in which three histidines bind to the catalytic zinc atom. The four-blade, C-terminal hemopexin-like domain, which is connected to the catalytic domain by a proline-rich hinge region, interacts with ECM components and can play a role in determining the substrate specificity in some MMPs. Gelatinases have these domains with additional insertions of collagen-binding type II repeats of fibronectin in the catalytic domain (see Figure 8-1); this provides them with collagen-binding properties. Matrilysins are the shortest, lacking the hemopexin-like domains. Furin-activated MMPs contain insertions of a basic motif with a cleavage site by proprotein convertases including furin at the end of the propeptide domains (see Figure 8-1).

Membrane-anchored MMPs include three different types of MMPs: type I transmembrane-type MMPs, GPI-linked MMPs, and type II transmembrane-type MMP. MMP-14, MMP-15, MMP-16, and MMP-24 (MT1-, MT2-, MT3-, and MT5-MMPs, respectively) have type I transmembrane domains in the C-terminal region, but MMP-17 (MT4-MMP) and MMP-25 (MT6-MMP) contain GPI anchors in the C-terminal region without transmembrane domains (see Figure 8-1). MMP-23 is unique in that it has type II transmembrane domain, a cysteine array, and an immunoglobulin-like domain instead of a hemopexin-like domain (see Figure 8-1).

Secreted-Type Matrix Metalloproteinases

Collagenases (MMP-1, MMP-8, and MMP-13). The collagenases include MMP-1 (interstitial collagenase, collagenase-1), MMP-8 (neutrophil collagenase, collagenase-2), and MMP-13 (collagenase-3). These MMPs attack triple helical regions of interstitial collagen types I, II, and III at a specific single site after the Gly residue of the partial sequences Gly-(Ile or Leu)-(Ala or Leu), located about three-fourths of the distance from the N-terminus. This cleavage generates fragments approximately three-fourths and one-fourth of the size of the collagen molecules.

Table 8-2 Substrates of Human Matrix Metalloproteinases

Enzymes	ECM Substrates	Non-ECM Substrates
Secreted-Type MMPs		
Collagenases		
MMP-1 (Interstitial collagenase)	Collagens I, II, III, VII, X; gelatins; aggrecan; link protein; entactin; tenascin; perlecan	α_2 -Macroglobulin; α_1 -PI; α_1 -antichymotrypsin; IGF-BP-2, -3, -5; pro-IL-1 β ; CTGF
MMP-8 (Neutrophil collagenase)	Collagens I, II, and III; gelatins; aggrecan; link protein	α_1 -PI
MMP-13 (Collagenase-3)	Collagens I, II, III, IV, IX, X, XIV; aggrecan; Fn; tenascin	CTGF; pro-TGF- β ; α_1 -antichymotrypsin
Gelatinases		
MMP-2 (Gelatinase A)	Gelatins; collagens IV, V, VII, XI; Ln; Fn; elastin; aggrecan; link protein	Pro-TGF- β ; FGF receptor I; MCP-3; IGF-BP-5; pro-IL-1 β ; galectin-3; plasminogen
MMP-9 (Gelatinase B)	Gelatins; collagens III, IV, V; aggrecan; elastin; entactin; link protein	Pro-TGF- β ; IL-2 receptor α ; Kit-L; IGF-BP-3; pro-IL-1 β ; α_1 -PI; galectin-3; ICAM-1; plasminogen
Stromelysins		
MMP-3 (Stromelysin-1)	Aggrecan; decorin; gelatins; Fn; Ln; collagens III, IV, IX, X; tenascin; link protein; perlecan	IGF-BP-3; pro-IL-1 β ; HB-EGF; CTGF; E-cadherin; α_1 -antichymotrypsin; α_1 -PI; α_2 -macroglobulin; plasminogen; uPA; proMMP-1, 7, 8, 9, 13
MMP-10 (Stromelysin-2)	Aggrecan; Fn; Ln; collagens III, IV, V; link protein	ProMMP-1, 8, 10
Matrilysins		
MMP-7 (Matrilysin-1)	Aggrecan; gelatins; Fn; Ln; elastin; entactin; collagen IV; tenascin; link protein	Pro- α -defensin; Fas-L; β 4 integrin; E-cadherin; pro-TNF; CTGF; HB-EGF; RANKL; IGF-BP-3; plasminogen
MMP-26 (Matrilysin-2)	Gelatin; collagen IV; Fn; fibrinogen	α_1 -PI; proMMP-9
Furin-Activated MMPs		
MMP-11 (Stromelysin-3)	Fn; Ln; aggrecan; gelatins	α_1 -PI; α_2 -macroglobulin; IGF-BP-1
MMP-28 (Epilysin)	Unknown	Casein
Other Secreted-Type MMPs		
MMP-12 (Metalloelastase)	Elastin; Fn; collagen V; osteonectin	Plasminogen; apolipoprotein A
MMP-19 (RASI-1)	Collagen IV; gelatin; Fn; tenascin; aggrecan; COMP; Ln; nidogen	IGF-BP-3
MMP-20 (Enamelysin)	Amelogenin; aggrecan; gelatin; COMP	Unknown
MMP-21	Unknown	Unknown
MMP-27	Unknown	Unknown
Membrane-Anchored MMPs		
Type I Transmembrane-Type MMPs		
MMP-14 (MT1-MMP)	Collagens I, II, III; gelatins; aggrecan; Fn; Ln; fibrin; Ln-5	ProMMP-2, 13; CD44; tissue transglutaminase
MMP-15 (MT2-MMP)	Fn; tenascin; nidogen; aggrecan; perlecan; Ln	ProMMP-2; tissue transglutaminase
MMP-16 (MT3-MMP)	Collagen III; Fn; gelatin	ProMMP-2; tissue transglutaminase
MMP-24 (MT5-MMP)	PG	ProMMP-2
GPI-Linked MMPs		
MMP-17 (MT4-MMP)	Gelatin; fibrinogen	Unknown
MMP-25 (MT6-MMP)	Gelatin; collagen IV; fibrin; Fn; Ln	ProMMP-2
Type II Transmembrane-Type MMP		
MMP-23	Gelatin	Unknown

COMP, cartilage oligomeric matrix protein; CTGF, connective tissue growth factor; ECM, extracellular matrix; Fn, fibronectin; GPI, glycosylphosphatidylinositol; HB-EGF, heparin-binding epidermal growth factor; IGF-BP, insulin-like growth factor binding protein; ICAM-1, intercellular adhesion molecule 1; RANKL, receptor activator for nuclear factor κ B ligand; IL-1, interleukin-1; Ln, laminin; MCP, monocyte chemoattractant protein; PG, proteoglycan; PI, proteinase inhibitor; TGF, transforming growth factor; TNF, tumor necrosis factor; uPA, urokinase-type plasminogen activator.

A biochemical study has disclosed the molecular mechanism of the cleavage: MMP-1 unwinds the triple helical structure by interacting with the $\alpha 2(I)$ chain of type I collagen and cleaves the three α chains in succession.⁹ MMP-13 is unique in that it cleaves α chains of type II collagen at two sites of the Gly⁹⁰⁶-Leu⁹⁰⁷ Gly⁹⁰⁹-Gln⁹¹⁰ bonds.¹⁰ All of

these collagenases degrade the interstitial collagens, but their specific activities against the collagens are different; MMP-1, MMP-8, and MMP-13 preferentially digest collagen types III, I, and II.^{10,11} Although rodents such as mice were originally thought to have only two collagenases (MMP-8 and MMP-13) and to lack the MMP-1 gene,

Table 8-3 Members of the ADAMTS Family

ADAMTS	Other Names	Demonstration of Proteinase Activity*	Functions and Biochemical Features	Tissue and Cell Expression
ADAMTS1	C3-C5; METH1; KIAA1346	+	Digestion of aggrecan and versican; binding to heparin	Kidney; heart; cartilage
ADAMTS2	Procollagen N-proteinase; hPCPN1; PCINP	+	Processing of collagen I and II N-propeptides	Skin; tendon
ADAMTS3	KIAA0366	+	Processing of collagen N-propeptides	Brain
ADAMTS4	KIAA0688; aggrecanase-1; ADMP-1	+	Digestion of aggrecan, brevican, and versican	Brain; heart; cartilage
ADAMTS5	ADAMTS11; aggrecanase-2; ADMP-2	+	Digestion of aggrecan	Uterus; placenta; cartilage
ADAMTS6	—	—	—	Placenta
ADAMTS7	—	—	—	Various tissues
ADAMTS8	METH-2	+	Digestion of aggrecan; inhibition of angiogenesis	Lung; heart
ADAMTS9	KIAA1312	+	Digestion of aggrecan	Cartilage
ADAMTS10	—	—	—	—
ADAMTS12	—	—	—	Lung (fetus)
ADAMTS13	VWFCP; C9orf8	+	Cleavage of von Willebrand factor	Liver; prostate; brain
ADAMTS14	—	+	Processing of collagen N-propeptides	Brain; uterus
ADAMTS15	—	+	Digestion of aggrecan	Liver (fetus); kidney (fetus)
ADAMTS16	—	+	Digestion of aggrecan	Prostate; brain; uterus
ADAMTS17	FLJ32769; LOC123271	—	—	Prostate; brain; liver
ADAMTS18	ADAMTS21; HGNC:16662	+	Digestion of aggrecan	Prostate; brain
ADAMTS19	—	—	—	Lung (fetus)
ADAMTS20	—	+	Digestion of versican (and aggrecan)	Brain; testis

*Proteinase activities are shown in 13 members of the ADAMTS family, but not in 6 other members.

rodent homologues of the human *MMP-1* gene were cloned and named mouse collagenase A and B (*Mcol-A* and *Mcol-B*).¹²

In addition to the interstitial fibrillar collagens, MMP-1, MMP-8, and MMP-13 degrade many other ECM macromolecules. MMP-1 digests entactin, collagen X, gelatins, perlecan, aggrecan, and cartilage link protein (see Table 8-2). MMP-8 digests aggrecan, gelatins, and cartilage link protein (see Table 8-2). MMP-13 hydrolyzes aggrecan; types IV, IX, X, and XIV collagens; fibronectin; and tenascin. Non-ECM substrates of MMP-1, MMP-8, and MMP-13 include α_2 -macroglobulin, α_1 -antiproteinase inhibitor, α_1 -antichymotrypsin, insulin-like growth factor binding protein (IGF-BP)-2 and IGF-BP-3, connective tissue growth factor (CTGF), and pro-TGF- β (see Table 8-2).

Gelatinases (MMP-2 and MMP-9). MMP-2 (gelatinase A) and MMP-9 (gelatinase B) belong to the gelatinase subgroup. Both MMPs readily digest gelatins and cleave collagen types IV and V.^{13,14} Elastin, aggrecan, and cartilage link protein also are substrates of the gelatinases. Although MMP-2 and MMP-9 share such substrates, they have different activities on several ECM macromolecules. MMP-2, but not MMP-9, digests fibronectin and laminin,¹³ and type III collagen and α_2 chains of type I collagen are degraded only by MMP-9.¹⁴ The gelatinases also process directly TGF- β into an active ligand (see Table 8-2). MMP-2 and MMP-9 cleave fibroblast growth factor receptor type I and interleukin (IL)-2 receptor type α (see Table 8-2). MMP-9 also releases soluble Kit-ligand.¹⁵ MMP-2 processes monocyte chemoattractant protein (MCP)-3 into an MCP-3 fragment

deleting the N-terminal four amino acids, which can bind to CC-chemokine receptors and act as a general chemokine antagonist.¹⁶

Stromelysins (MMP-3 and MMP-10). The subgroup of stromelysins consists of MMP-3 (stromelysin-1) and MMP-10 (stromelysin-2). They share 78% identity in amino acid sequence and have similar enzymatic properties.¹⁷ The enzymes hydrolyze numerous ECM macromolecules including aggrecan, fibronectin, laminin, and collagen IV (see Table 8-2).¹⁸ Collagen types III, IX, and X and telopeptides of collagen types I, II, and XI also are digested by MMP-3.¹⁹ In addition to the ECM components, MMP-3 is active on IGF-BP-3, IL-1 β , heparin-binding epidermal growth factor (HB-EGF), CTGF, E-cadherin, α_1 -antichymotrypsin, and α_1 -proteinase inhibitor (see Table 8-2). MMP-3 also activates many proMMPs.⁶ A similar activator function has been identified for MMP-10.²⁰

Matrilysins (MMP-7 and MMP-26). Matrilysins include MMP-7 (matrilysin-1) and MMP-26 (matrilysin-2), which are the smallest of the MMPs, having only the propeptide and catalytic domains. The substrate specificity of MMP-7 is similar to that of stromelysins, digesting numerous ECM components including aggrecan; gelatins; fibronectin; laminin; elastin; entactin; collagen types III, IV, V, IX, X, and XI; fibrin/fibrinogen; vitronectin; tenascin; and link protein (see Table 8-2). Although these substrates overlap with the substrates of other MMPs, the specific activity of MMP-7 to most substrates is highest among the MMPs.^{21,22} Non-ECM molecules such as α -defensin, Fas ligand, β_4 integrin, E-cadherin, plasminogen, tumor necrosis factor

Table 8-4 Members of the Human ADAM Family

ADAM	Other Names	Proteinase-Type (P) or Non-Proteinase-Type (NP)	Functions and Biochemical Features	Tissue and Cell Expression
ADAM2	PH-30 β ; Fertilin- β	NP	Sperm/egg binding/fusion; binding to integrin $\alpha\beta 1$, $\alpha 6\beta$, and $\alpha 9\beta$	Sperm
ADAM7	EAP I; GP-83	NP	Binding to integrin $\alpha 4\beta 1$, $\alpha 4\beta 7$, and $\alpha 9\beta 1$	Testis
ADAM8	MS2 (CD156)	P	Neutrophil infiltration; shedding of CD23	Macrophages; neutrophils
ADAM9	MDC9; MCMP; Meltrin- γ	P	Shedding of HB-EGF, TNF-p75 receptor; and APP; digestion of fibronectin and gelatin; binding to integrin $\alpha 2\beta 1$, $\alpha 6\beta 1$, $\alpha 6\beta 4$, $\alpha 9\beta 1$, and $\alpha V\beta 5$	Various tissues
ADAM10	MDAM; Kuzbanian	P	Shedding of TNF, Delta, Delta-like 1, Jagged, N-cadherin, E-cadherin, VE-cadherin, Ephrin A2, Ephrin A5, Fas-I, IL6R, APP, L1, CD44, and HB-EGF; digestion of collagen IV, gelatin, and myelin basic protein; presence of RRKR sequence	Kidney; brain; chondrocytes
ADAM11	MDC	NP	Tumor suppressor gene (?)	Brain
ADAM12	Meltrin- α ; MCMP; MLTN; MLTNA	P	Muscle formation; presence of RRKR sequence; binding to integrin $\alpha 4\beta 1$ and $\alpha 9\beta 1$; digestion of IGF-BP-3 and -5; shedding of HB-EGF, and epiregulin; digestion of collagen IV, gelatin, and fibronectin	Osteoblasts; muscle cells; chondrocytes; placenta
ADAM15	Metargidin; MDC15; AD56; CR II-7	P	Expression in arteriosclerosis; binding to integrin $\alpha v\beta 3$, $\alpha 5\beta 1$, and $\alpha 9\beta 1$; digestion of collagen IV and gelatin; shedding of CD23	Smooth muscle cells; chondrocytes; endothelial cells; osteoclasts
ADAM17	TACE; cSVP	P	Shedding of TNF, TGF- β , TNF-p75 receptor, RANKL, amphiregulin, epiregulin, HB-EGF, APP, L-selectin, and CD44; presence of RRKR sequence; binding to integrin $\alpha 5\beta 1$	Macrophages; various tissues; carcinoma tissue
ADAM18	tMDC III	NP	—	Testis
ADAM19	Meltrin- β ; FKSG34	P	Formation of neuron; shedding of neuregulin, and RANKL; binding to integrin $\alpha 4\beta 1$ and $\alpha 5\beta 1$	Testis
ADAM20	—	P	Formation of sperm	Testis
ADAM21	—	P	—	Testis
ADAM22	MDC2	NP	—	Brain
ADAM23	MDC3	NP	Binding to integrin $\alpha v\beta 3$	Brain; heart
ADAM28	e-MDC II; MDC-Lm; MDC-Ls	P	Digestion of myelin basic protein, IGF-BP-3, and CTGF; shedding of CD23; binding to integrin $\alpha 4\beta 1$, $\alpha 4\beta 7$, and $\alpha 9\beta 1$	Testis; lung; lymphocytes; pancreas; uterus
ADAM29	svph 1	NP	—	Testis
ADAM30	svph 4	P	—	Testis
ADAM32	AJ131563	NP	—	Testis
ADAM33	—	P	Mutation in bronchial asthma patients; shedding of APP and KL-1; digestion of insulin B chain; binding to integrin $\alpha 4\beta 1$, $\alpha 5\beta 1$, and $\alpha 9\beta 1$	Lung (fibroblasts, smooth muscle cells)
ADAMDEC1	—	P	—	Lymphatic system; gastrointestinal system

ADAMDEC1, ADAM-like decysin 1; APP, amyloid precursor protein; CTGF, connective tissue growth factor; HB-EGF, heparin-binding epidermal growth factor; IGF-BP, insulin-like growth factor binding protein; IL6R, interleukin-6 receptor; RANKL, receptor activator of nuclear factor κB ligand; TGF, transforming growth factor; TNF, tumor necrosis factor.

(TNF), and CTGF also are the substrates for MMP-7 (see Table 8-2). MMP-26 degrades gelatin, type IV collagen, fibronectin, fibrinogen, and α_1 -proteinase inhibitor,²³⁻²⁵ but information about other substrates is still limited.

Furin-Activated Matrix Metalloproteinases (MMP-11 and MMP-28). MMP-11 (stromelysin-3) and MMP-28 (epilysin) contain an RKRR sequence at the end of the

propeptide, which is a unique motif for intracellular processing of proproteins to mature molecules by furin and other proprotein convertases. ProMMP-11 is activated intracellularly by the action of furin.²⁶ MMP-11 shows only weak proteolytic activity against gelatin, laminin, fibronectin, and aggrecan,²⁷ but it has respectable catalytic action in digesting α_1 -proteinase inhibitor, α_2 -macroglobulin, and

Figure 8-1 Domain structures of two types of matrix metalloproteinases (MMPs) (secreted-type MMP and membrane-anchored MMP) and two types of a disintegrin and metalloproteinase (ADAMs) (a disintegrin and metalloproteinase with thrombospondin motifs [ADAMTS] and membrane-type ADAM). The typical domain structure of most secreted-type MMPs (collagenases, stromelysins, and other MMPs) is composed of a prodomain, catalytic domain, hinge, and hemopexin-like domain. Gelatinases (MMP-2 and MMP-9) have additional insertions of collagen-binding type II repeats of fibronectin in the catalytic domain, whereas matrilysins (MMP-7 and MMP-26) lack a hemopexin-like domain. Furin-activated MMPs (MMP-11 and MMP-28) contain an RKRR sequence (furin recognition site = F) at the end of the propeptide. Membrane-anchored MMPs are composed of type I transmembrane-type MMPs (MT1-, MT2-, MT3-, MT5-MMPs); GPI-linked MMPs (MT4, MT6-MMPs); and type II transmembrane-type MMP (MMP-23). All of them have furin recognition sites. ADAMTS has a prodomain, a furin recognition site (F), a catalytic domain, a hinge, a disintegrin domain (D), thrombospondin motifs (Ts), and a spacer domain (S). Membrane-type ADAM is composed of a prodomain, furin recognition site (F), catalytic domain, hinge, disintegrin domain (D), cysteine-rich domain (C), EGF-like domain (E), and transmembrane domain (Tm).

IGF-BP-1 (see Table 8-2).^{28,29} MMP-28 can degrade casein, but its natural substrates are unknown.³⁰

Other Secreted-Type Matrix Metalloproteinases (MMP-12, MMP-19, MMP-20, MMP-21, and MMP-27). MMP-12 (metalloelastase),³¹ MMP-19 (RASI-1),³² MMP-20 (enamelysin),³³ MMP-21,²⁵ and MMP-27 have structural characteristics similar to collagenases and stromelysins. These MMPs are not classified into the previously mentioned subgroups, however, because their substrates and other biochemical characters are not fully examined at present. Overall information on the substrate specificity of MMP-12,³¹ MMP-19,^{34,35} and MMP-20^{33,35} suggests that they are stromelysin-like proteinases. MMP-12³¹ digests elastin, fibronectin, collagen V, osteonectin, and plasminogen (see Table 8-2). MMP-19, which was originally reported as MMP-18 but renamed as MMP-19, cleaves type IV collagen, laminin, fibronectin, gelatin, tenascin, entactin, fibrin/fibrinogen, aggrecan, and cartilage oligomeric matrix protein (COMP) (see Table 8-2).^{34,35} MMP-20 also digests amelogenin, aggrecan, and COMP.³⁵ Substrates of MMP-21 and MMP-27 are unknown, however.

Membrane-Anchored Matrix Metalloproteinases

Type I Transmembrane-Type MMPs. These include MMP-14 (MT1-MMP),³⁶ MMP-15 (MT2-MMP),³⁷ MMP-16 (MT3-MMP),³⁸ and MMP-24 (MT5-MMP).³⁹ All of these MT-MMPs can activate proMMP-2, but MMP-14 may play a major role in the activation of proMMP-2 in various tissues (see later). Besides the activator function, however, MMP-14 digests the triple helical portions of interstitial collagen types I, II, and III and other ECM components including fibronectin, laminin, aggrecan, and gelatin (see Table 8-2).⁴⁰ MMP-15 also digests fibronectin, tenascin, nidogen, aggrecan, perlecan, and laminin.⁴¹ MMP-16 cleaves collagen type III, fibronectin, and gelatins.⁴² MMP-17 (MT4-MMP)⁴³ and MMP-25 (MT6-MMP)⁴⁴ are GPI-linked MMPs. MMP-17 and MMP-25 can digest gelatin and fibrin/fibrinogen (see Table 8-2).⁴⁴⁻⁴⁶ MMP-23 (cysteine array-MMP, MIFR) is a type II transmembrane-type MMP⁴⁷; almost identical genes are cloned, called MMP-23A and MMP-23B. MMP-23 digests gelatin,⁴⁸ but no information about other substrates is available (see Table 8-2). A unique aspect of MMP-23 is that this MMP is

expressed in only female and male reproductive organs such as endometrium, ovary, testis, and prostate,⁴⁸ but its functions are not well established.

ADAM and ADAMTS Families

Two ADAM (a disintegrin and metalloproteinase) gene families exist: membrane-type ADAM with transmembrane domain (ADAM) and secreted-type ADAM with thrombospondin motifs (ADAMTS) (see [Figure 8-1](#)). The active sites in the catalytic domains of most members of both gene families contain a common sequence of HEXGHXXGXXHD with the “Met-turn,” which also is present in MMP members.

The ADAMTS family includes 19 members. Although information about substrates and biologic functions is still limited, ADAMTS1, ADAMTS2, ADAMTS3, ADAMTS4, ADAMTS5, ADAMTS8, ADAMTS9, ADAMTS14, ADAMTS15, ADAMTS16, ADAMTS18, and ADAMTS20 all are ECM-degrading proteinases (see [Table 8-3](#)). ADAMTS1,⁴⁹ ADAMTS4,⁵⁰ ADAMTS5,⁵¹ ADAMTS8, ADAMTS9, and ADAMTS15 can preferentially cleave aggrecan at the five Glu-X bonds including the Glu³⁷³-Ala³⁷⁴ bond (the aggrecanase site). Because of aggrecan-degrading activity, ADAMTS4 and ADAMTS5 are named aggrecanase-1 and aggrecanase-2^{50,51}; versican also is digested by these proteinases,⁵² and brevican is cleaved by ADAMTS4 (see [Table 8-3](#)).⁵³ The C-terminus-truncated ADAMTS4 also degrades fibromodulin and decorin.⁵⁴ ADAMTS16, ADAMTS18, and ADAMTS20 also appear to have weak aggrecanase activity. ADAMTS2 and ADAMTS3 process the N-terminal propeptides of type I and II collagens and are named procollagen N-proteinase. Activity of procollagen N-proteinase also is known with ADAMTS14. ADAMTS13 is a von Willebrand factor-cleaving proteinase, and its mutation causes thrombotic thrombocytopenic purpura. Proteinase activities of other ADAMTS species are still unknown.

The human genome contains 25 ADAM genes including 4 pseudogenes, and thus the human ADAM family is composed of 21 members ([Table 8-4](#)). Among the ADAMs, ADAM8, ADAM9, ADAM10, ADAM12, ADAM15, ADAM17, ADAM19, ADAM20, ADAM21, ADAM28, ADAM30, ADAM33, and ADAMDEC1 exhibit proteolytic activity (proteinase-type ADAMs) (see [Table 8-4](#)). Although ADAM10, ADAM12, and ADAM15 degrade type IV collagen, the main substrates of these ADAMs are various membrane proteins, which include precursors of cytokines and growth factors such as TNF, HB-EGF and neuregulin, IGF-BPs, receptors such as p75 TNF receptor, IL-1 receptor II, and other membrane proteins related to development such as Notch ligand and ephrin (see [Table 8-4](#)).⁵⁵⁻⁶⁰ According to these data, a major function of the ADAMs is shedding of the membrane proteins. ADAM17 cleaves a proform of TNF at the physiologic processing site into the soluble form of TNF and is called *TNF-converting enzyme*. ADAM17 also is involved in release of L-selectin, TGF- α , and p75 TNF receptor.⁵⁵ ADAM9, ADAM12, and ADAM17 can shed HB-EGF from its precursor. ADAM12 and ADAM28 cleave IGF-BP-3 and IGF-BP-5.^{60,61} CD23 is shed by ADAM8, ADAM15, and ADAM28.⁶² Other functions of ADAMs include binding to integrins, cell-cell

interaction, cell migration, and signal transduction (see [Table 8-4](#)).⁶³

ENDOGENOUS PROTEINASE INHIBITORS

Endogenous proteinase inhibitors control the activities of proteinases in vivo. The inhibitors are derived from plasma or cells in the local tissues. Plasma contains several proteinase inhibitors, and about 10% of all the plasma proteins are proteinase inhibitors. Most are proteinase class specific, but α_2 -macroglobulin inhibits the activities of proteinases from all four groups. Major endogenous inhibitors of the ECM-degrading proteinases are listed in [Table 8-5](#).

α_2 -Macroglobulin

The α_2 -macroglobulin molecule is a large plasma glycoprotein of 725 kD, which consists of four identical subunits of 185 kD that are linked in pairs by disulfide bonds. The pairs assemble noncovalently. Almost all active proteinases, regardless of the proteinase classes, bind and attack the so-called bait region, located near the center of the subunit. After cleaving within the bait region, the proteinase is physically trapped within the molecule by inducing a conformational change of the inhibitor, resulting in a proteinase/ α_2 -macroglobulin complex. Although the proteinase in the complex remains active against small substrates, it is trapped by the arms of the α_2 -macroglobulin from degrading larger proteins. Besides the function as a proteinase inhibitor, α_2 -macroglobulin may act as a carrier protein because it also binds to numerous growth factors and cytokines such as platelet-derived growth factor, basic fibroblast growth factor, TGF- β , insulin, and IL-1 β .

The α_2 -macroglobulin molecule is synthesized mainly in liver, but also locally by macrophages, fibroblasts, and adrenocortical cells. Concentration of the inhibitor in plasma is 250 mg/dL. Because of its large molecular weight, it is not present in noninflammatory synovial fluid. During synovial inflammation, α_2 -macroglobulin penetrates into the joint cavity. Rheumatoid synovial fluid has about the same concentration of the inhibitor as plasma.

Inhibitors of Serine Proteinases

The primary inhibitors of serine proteinases include the members of the serpin (serine proteinase inhibitor) gene family, Kunitz-type inhibitors, and others (see [Table 8-5](#)). The serpins are glycoproteins of 50 to 100 kD and share homology with human α_1 -proteinase inhibitor.⁶⁴ The major serpins involved in the regulation of ECM-degrading serine proteinases are α_1 -proteinase inhibitor, α_1 -antichymotrypsin, α_2 -antiplasmin, plasminogen activator inhibitors (PAI-1 and PAI-2), protein C inhibitor (PAI-3), C1-inhibitor, kallistatin, and proteinase nexin-1 (PN-1). The main proteinases inhibited by these molecules are listed in [Table 8-5](#). Although PAI-1 and PAI-2 inhibit tPA and uPA, the inhibition by PAI-1 and PAI-2 is more effective to tPA and uPA, respectively.

Kunitz-type inhibitors include aprotinin, trypstatin, and PN-2, which is identical to a β -amyloid protein precursor. Secretory leukocyte proteinase inhibitor, which inhibits

Table 8-5 Endogenous Inhibitors of Extracellular Matrix–Degrading Proteinases

Inhibitor	Molecular Mass (kD)	Source	Target Enzyme
α_2 -Macroglobulin	725	Plasma (liver); macrophages; fibroblasts	Most proteinases from all classes
Inhibitors of Serine Proteinase			
<i>Serpins</i>			
α_1 -Proteinase inhibitor	52	Plasma; macrophages	Neutrophil elastase, cathepsin G, proteinase 3
α_1 -Antichymotrypsin	58	Plasma	Cathepsin G; chymotrypsin; chymase; tissue kallikrein
α_2 -Antiplasmin	67	Plasma	Plasmin
Proteinase nexin-1	45	Fibroblasts	Thrombin; uPA; tPA; plasmin; trypsin; trypsin-like serine proteinase
PAI-1	45	Endothelial cells; fibroblasts; platelets; plasma	tPA; uPA
PAI-2	47	Plasma; macrophages	uPA; tPA
Protein C inhibitor	57	Plasma; urine	Active protein C; tPA; uPA; tissue kallikrein
C1-inhibitor	96	Plasma	Plasma kallikrein; C1 esterase
Kallistatin	92	Plasma; liver; stomach; kidney; pancreas	Tissue kallikrein
<i>Kunins</i>			
Aprotinin	7	Mast cells	Plasmin; kallikrein
Trypsin	6	Mast cells	Tryptase
Proteinase nexin-2 (β -amyloid protein precursor)	100	Fibroblasts	EGF binding protein, NGF- γ , trypsin, chymotrypsin, factor Xla
<i>Others</i>			
SLPI	15	Bronchial secretions; seminal plasma; cartilage	Neutrophil elastase; cathepsin G; chymotrypsin; trypsin
Elafin	7	Horny layers of skin	Neutrophil elastase; proteinase 3
Inhibitors of Cysteine Proteinase			
Stefin A	11	Cytosol	Cysteine proteinases
Stefin B	11	Cytosol	Cysteine proteinases
Cystatin C	13	Body fluids	Cysteine proteinases
Cystatin S	13	Seminal plasma; tears; saliva	Cysteine proteinases
Kininogens	50-78/108-120	Plasma	Cysteine proteinases
Calpastatin	120	Cytosol	Calpains
Metalloproteinase Inhibitors			
TIMP-1	28	Connective tissue cells; macrophages	MMPs
TIMP-2	22	Connective tissue cells; macrophages	MMPs
TIMP-3	21/24*	Fibroblasts; synovial cells	MMPs; ADAMs; ADAMTS
TIMP-4	21	Heart; brain; testis	MMPs
RECK	110	Many tissue cells; fibroblasts	MMP-2; MMP-7; MMP-14 (MT1-MMP); ADAM10

*Glycosylated form.

EGF, epidermal growth factor; NGF, nerve growth factor; PA, plasminogen activator; PAI, plasminogen activator inhibitor; RECK, reversion-inducing, cysteine-rich protein with Kazal motifs; SLPI, secretory leukocyte proteinase inhibitor; TIMP, tissue inhibitor of metalloproteinases; tPA, tissue-type plasminogen activator; uPA, urokinase-type plasminogen activator.

neutrophil elastase and cathepsin G, is present in many secretory and inflammatory fluids and in cartilage. Elafin is a serine proteinase inhibitor with 38% identity with the second domain of secretory leukocyte proteinase inhibitor; it inhibits neutrophil elastase and proteinase 3.

Inhibitors of Cysteine Proteinases

The members of the cystatin superfamily and calpastatin belong to the family of inhibitors of ECM-degrading cysteine proteinases (see Table 8-5). Cystatins capable of

inhibiting lysosomal cysteine proteinases consist of three groups. Subgroup 1 comprises stefins A and B. Each has a molecular mass of 11 kD, and the stefins reside within cells. Subgroup 2 comprises cystatin C and S, each with a molecular mass of 13 kD. They occur at relatively high concentrations in cerebrospinal fluid and saliva. Subgroup 3 comprises the kininogens. Kininogens that participate in blood coagulation and inflammation also are inhibitors of cysteine proteinases. Calpains are not inhibited by cystatins but are inhibited by calpastatin (120 kD), which is a cytosolic-specific inhibitor of calpain.

Tissue Inhibitors of Metalloproteinases

TIMPs are a gene family consisting of four different members with approximately 40% to 50% sequence identity (i.e., *TIMP-1*, *TIMP-2*, *TIMP-3*, and *TIMP-4*), which have molecular masses ranging from 21 to 28 kD in humans.⁶⁵⁻⁶⁹ Virtually all TIMPs inhibit the activities of MMPs by binding in a 1:1 molar ratio to form tight, noncovalent complexes⁶⁵ except that *TIMP-1* does not inhibit efficiently MT-MMPs.^{41,42,70} TIMPs contain 12 highly conserved cysteine residues that form six intrachain disulfide bonds, which are essential for maintaining the correct ternary structure of the molecule^{67,71} and stable inhibitor activity.⁶⁵ The TIMP molecules have two structurally distinct subdomains: an N-terminal subdomain that consists of loops 1 through 3 and a C-terminal subdomain that consists of loops 4 through 6. The N-terminal subdomain of each TIMP molecule contains the inhibitory activity for MMPs.⁶⁵ Studies on the crystal structures of the MMP/TIMP complexes show that the wedge-shaped TIMPs bind with their edge into the entire length of the active-site cleft of their cognate MMPs.⁶⁷ High affinity and efficient inhibitor activity of *TIMP-2* to MMP-14 (MT1-MMP) are explained by the interaction between a quite long hairpin loop of *TIMP-2* and a loop over the rim of the active-site cleft of MMP-14.⁷²

TIMP-1 and *TIMP-2* are unique in that they make the complexes with proMMP-9 and proMMP-2 (i.e., the proMMP-9/*TIMP-1* and proMMP-2/*TIMP-2* complexes). Similar complex formation also is known between *TIMP-4* and proMMP-2. Because the complexes are made through the interaction between their C-termini,⁶⁵ TIMPs in the complexes retain inhibitor activity against MMPs. The activation of proMMP-9 and proMMP-2 is suppressed in the complex forms; the complex formation may be a safety device for these gelatinases.¹⁴ The proMMP-2/*TIMP-2* complex is useful for the efficient activation of proMMP-2 by MMP-14 on the cell membranes because MMP-14 captures proMMP-2 to the cell membranes through the trimolecular complex formation between the catalytic domain of MMP-14 and the N-terminal domain of *TIMP-2* (see later).^{73,74}

Besides the inhibition and interactions of TIMPs to MMPs, *TIMP-3*, among the TIMPs, most efficiently inhibits the activities of ADAM10, ADAM12, ADAM17, ADAM28, and ADAM33,⁷⁵ although ADAM8, ADAM9, and ADAM19 are not inhibited by TIMPs. Because *TIMP-3* also efficiently inhibits the aggrecan-degrading activity of ADAMTS4 and ADAMTS5, *TIMP-3* may be a common tissue inhibitor of the ADAM members. The N-terminal subdomain of *TIMP-3* is critical to the inhibition of the activities of ADAM members and MMPs, but the inhibition mechanism seems to be different.⁷⁶ TIMPs are multifunctional proteins with more diverse actions than MMP/ADAM inhibitors including growth factor activity, antian angiogenic activity, and regulatory activity of apoptosis.⁶⁹

Another new MMP inhibitor is *RECK* (reversion-inducing, cysteine-rich protein with Kazal motifs).⁷⁷ *RECK* is a GPI-linked glycoprotein harboring three inhibitor-like domains and inhibits the activities of at least MMP-2, MMP-7, MMP-9, MMP-14, and ADAM10. Although this inhibitor seems to play a key role in the angiogenic

processes in vivo, its biochemical mechanism as an inhibitor to the MMPs and ADAM10 and functions in pathologic conditions such as arthritides remain unknown.

REGULATION OF PROTEINASE ACTIVITY

The activities of ECM-degrading proteinases in tissues are regulated by the balance between the proteinases and their inhibitors. The balance at the local tissues depends on several factors including production rates of proteinases and inhibitors, their secretion, activation of proenzymes, and anchoring systems of the activated proteinases to cell surfaces. Production levels of the proteinases and inhibitors within the cells are controlled mainly by their gene expression. Activation processes of proMMPs and membrane anchoring of their activities have been established by extensive experimental work.

Gene Expression of Proteinases and Inhibitors

Matrix Metalloproteinases and Tissue Inhibitors of Metalloproteinases

Normal cells except for inflammatory cells produce only limited levels of MMPs or TIMPs in the tissues under physiologic conditions, but their expression is stimulated by many factors under pathologic conditions. Neutrophils and macrophages synthesize MMP-8 and MMP-9 during the differentiation and store them within the granules of the differentiated cells. Tumor cells express many MMPs such as MMP-1, MMP-7, MMP-9, MMP-10, and MMP-14 (MT1-MMP) and *TIMP-1* predominantly by oncogenic transformation. The gene expression of MMPs and TIMPs in the tissue cells other than inflammatory cells and tumor cells is regulated by numerous factors, however, including cytokines, growth factors, and chemical and physical stimuli.

Much information is available for regulators of MMP-1 and MMP-3, which are coordinately expressed in many cell types after stimulation with cytokines and growth factors, factors acting at the cell surface, and chemical agents (Table 8-6). The induced production of MMP-1 and MMP-3 is suppressed by retinoic acid, TGF- β , and glucocorticoid. The gene expression of MMP-7 and MMP-9 is regulated by similar factors, but the regulation is stricter and fewer factors modulate the expression (see Table 8-6). MMP-14 expression is upregulated by phorbormyristate acetate (12-O-tetradecanoylphorbol-13-acetate), concanavalin A, basic fibroblast growth factor, and TNF, and it is downregulated by glucocorticoids in various cells. TNF and IL-1 α stimulate osteoarthritic chondrocytes to express the MMP-14 gene.⁷⁸ In contrast to these MMPs, MMP-2 and *TIMP-2* are unique in that factors capable of enhancing the production of MMP-1, MMP-3, and *TIMP-1* are inactive.

TIMP-1 expression is enhanced or suppressed in response to many factors including cytokines, growth factors, and oncogenic transformation (see Table 8-6). Effects of these stimulatory factors are common to the gene expression of MMPs, but they are regulated independently. TGF- β , retinoic acid, progesterone, and estrogen enhance *TIMP-1* expression in fibroblasts, but they suppress the expression of

Table 8-6 Factors That Modulate Synthesis of Matrix Metalloproteinases and Tissue Inhibitors of Metalloproteinases

Enzyme or TIMP	Stimulating Factor*	Suppressive Factor
MMP-1	Cytokines and growth factors: IL-1; TNF; EGF; PDGF; bFGF; VEGF; NGF; TGF- α ; IFN- α ; IFN- β ; IFN- γ ; leukoregulin; relaxin Factors acting at cell surface: calcium ionophore A23187; cell fusion; collagen; concanavalin A; integrin receptor antibody; crystals of urate, hydroxyapatite, and calcium pyrophosphate; SPARC (osteonectin/BM 40); iron; extracellular matrix metalloproteinase inducer (EMMPRIN/CD147/basigin/M6 antigen); phagocytosis Chemical agents: cAMP; colchicine; cytochalasins B and D; LPS; pentoxifylline; TPA; calmodulin inhibitors; serotonin; 1,25-(OH) $_2$ vitamin D $_3$; platelet-activating factor; serum amyloid A; β -microglobulin Physical factors: heat shock; ultraviolet irradiation Others: viral transformation; oncogenes; autocrine agents; aging of fibroblasts	Retinoic acids; glucocorticoids; estrogen; progesterone; TGF- β ; transmembrane neural cell adhesion molecule; cAMP; IFN- γ ; adenovirus E1A
MMP-2	TGF- β ; concanavalin A; H-ras transformation; extracellular matrix metalloproteinase inducer (EMMPRIN/CD147/basigin/M6 antigen)	Adenovirus E1A
MMP-3	IL-1; TNF; EGF; concanavalin A; SPARC (osteonectin/BM 40); LPS; TPA; extracellular matrix metalloproteinase inducer (EMMPRIN/CD147/basigin/M6 antigen); viral transformation; oncogenes; integrin receptor antibody; heat shock; calcium ionophore A23187; cytochalasin B	Retinoic acids; glucocorticoids; estrogen; progesterone; TGF- β ; adenovirus E1A

MMP-13	bFGF; TNF; TGF- β	Unknown
MMP-14 (MT1-MMP)	Concanavalin A; TPA; bFGF; TNF; IL-1 α	Glucocorticoids
TIMP-1	IL-1; IL-6; IL-11; TPA; TGF- β ; TNF; retinoic acids; LPS; progesterone; estrogen; oncogenic transformation; viral infection	Extracellular matrix; cytochalasins
TIMP-2	Progesterone	TGF- β ; LPS
TIMP-3	EGF; TGF- β ; TPA; TNF; glucocorticoids; oncostatin M	Unknown

*Factors regulating gene expression of other MMPs excluded from this table and TIMP-4 are unknown.

bFGF, basic fibroblast growth factor; cAMP, cyclic adenosine monophosphate; EGF, epidermal growth factor; IFN, interferon; IL, interleukin; LPS, lipopolysaccharide; NGF, nerve growth factor; PDGF, platelet-derived growth factor; TGF, transforming growth factor; TNF, tumor necrosis factor; TPA, 12-O-tetradecanoylphorbol-13-acetate; VEGF, vascular endothelial growth factor.

MMP-1 and MMP-3. Although information about stimulating and suppressive factors of *TIMP-1*, *TIMP-2*, and *TIMP-3* is available (see Table 8-6), factors controlling the gene expression of *TIMP-4* are not well known. Previous studies have identified the elements in the promoters of MMPs and TIMPs, which are related to or responsible for the stimulation or suppression of the gene expression with various factors. Regulation of the gene expression is generally explained by the structural characteristics of the promoters.

Serine Proteinases and Their Inhibitors

Neutrophil elastase, cathepsin G, chymase, and tryptase are stored within the secretory granules and secreted into the extracellular milieu after activation of neutrophils and mast cells. The expression of these serine proteinases is controlled mainly by the cellular differentiation. Precursors of plasmin and plasma kallikrein are constitutively synthesized predominantly in liver, circulate in blood as zymogen forms (i.e., plasminogen and prekallikrein), and reach the inflamed tissues by being released from blood vessels. The proteinase activities in the tissues are controlled mainly through activation of the proenzymes by activators. The uPA and tPA molecules, activators of plasminogen, are synthesized by

tissue cells, and their gene expression is regulated by many factors (Table 8-7). The uPA synthesis is upregulated in many normal cell types and in transformed cells by agents that increase intracellular cyclic adenosine monophosphate (cAMP) levels (e.g., calcitonin, vasopressin, cholera toxin, cAMP analogues); growth factors (e.g., EGF, platelet-derived growth factor, vascular endothelial growth factor); cytokines (IL-1, TNF); and phorbol esters, whereas glucocorticoid decreases the expression.⁸ The expression of tPA is regulated by similar factors (see Table 8-7). In endothelial cells, proteinases are enhancers; thrombin and plasmin stimulate the production of tPA.⁸ PAI-1 and PAI-2 also are regulated by common factors, many of which also enhance the production of uPA and tPA (see Table 8-7). Most serpins are constitutively produced in liver and secreted to plasma.

Lysosomal Cysteine and Aspartic Proteinases

The expression of lysosomal cysteine proteinases, *cathepsins B*, *L*, and *K*, is generally constitutive, but cellular transformation is often associated with increased synthesis of cathepsins B and L. Cathepsin B transcription varies with cell type and the state of differentiation of tumor cells; it is increased in chondrocytes by IL-1. Malignant transformation, tumor promoters, and growth factors stimulate the

Table 8-7 Factors That Regulate Expression of Plasminogen Activators and Their Inhibitors

Enzyme or Inhibitor	Stimulatory Factor	Suppressive Factor
uPA	TPA; IL-1; IFN- γ ; EGF; PDGF; bFGF; VEGF; TGF- β ; cholera toxin; cAMP; estrogen; calcitonin; vasopressin; disruption of E-cadherin-dependent cell-cell adhesion	Glucocorticoids; TGF- β
tPA	TPA; EGF; bFGF; VEGF; retinoic acids; glucocorticoids; cAMP; thrombin; plasmin; follicle-stimulating hormone; luteinizing hormone; gonadotropin-releasing hormone	TNF
PAI-1	IL-1; TNF; TGF- β ; bFGF; VEGF; TPA; glucocorticoids	cAMP
PAI-2	TPA; LPS; TNF; colony-stimulating factor; cholera toxin; dengue virus	Glucocorticoids
PN-1	TPA; EGF; thrombin	Unknown

bFGF, fibroblast growth factor; cAMP, cyclic adenosine monophosphate; EGF, epidermal growth factor; IFN, interferon; IL, interleukin; LPS, lipopolysaccharide; PAI, plasminogen activator inhibitor; PDGF, platelet-derived growth factor; PN, proteinase nexin; TGF, transforming growth factor; TNF, tumor necrosis factor; TPA, 12-O-tetradecanoylphorbol-13-acetate; tPA, tissue-type plasminogen activator; uPA, urokinase-type plasminogen activator; VEGF, vascular endothelial growth factor.

synthesis of cathepsin L. *Cathepsin K* gene expression in monocyte-macrophage lineage depends on the cellular differentiation to osteoclasts, but all-*trans* retinoic acid upregulates the expression in rabbit osteoclasts. Lysosomal aspartic proteinase, *cathepsin D*, is constitutively expressed in almost all cells, although estradiol, calcitriol, and retinoic acid can regulate the expression.

Activation Mechanisms of the Zymogens of Matrix Metalloproteinases

All of the MMPs are synthesized as inactive zymogens (proMMPs), and activation of proMMPs is prerequisite to their functioning in vivo. ProMMPs are kept inactive by an interaction between a cysteine-sulphydryl group in the conserved propeptide sequence PRCGXPD and the zinc ion bound to the catalytic domain, preventing the formation of a water-zinc complex that is essential to the enzymatic reaction. Activation requires proteolytic removal of the propeptide domain. There are three pathways of proMMP activation—extracellular, intracellular, and pericellular (Figure 8-2).

Extracellular Activation

Extracellular activation, which is applicable to many secreted MMPs (e.g., proMMP-1, proMMP-3, proMMP-7, proMMP-8, proMMP-9, proMMP-10, proMMP-12, proMMP-13), is initiated through the disruption of the Cys-Zn²⁺ interaction by treatment with nonproteolytic agents or proteinases and completed by autocatalytic processing.^{6,69} Nonproteolytic activators used in vitro include thiol-modifying reagents (e.g., mercurial compounds, iodoacetamide, *N*-ethylmaleimide, oxidized glutathione), hypochlorous acid, sodium dodecyl sulfate, chaotropic agents, and physical factors (heat and acid exposure).⁶ Most of these factors, especially 4-aminophenylmercuric acetate (APMA), enable proMMP molecules to generate a short-lived intermediate, which is formed by removal of a part of propeptide by an intramolecular reaction.⁶ The fully activated form is made by an intermolecular autocatalysis cleaving three amino acids downstream from the conserved sequence PRCGXPD and leading to generation of active MMPs starting with Tyr or Phe at the N-terminus. Such a process may not be essential, however, for proMMP-9 activation by APMA because a fully active form retaining the PRCGVDP sequence is generated by the cleavage of the

Ala⁷⁴-Met⁷⁵ bond upstream of the conserved sequence.¹⁴ Concerning proMMP-9 activation during cerebral ischemia in vivo, nitric oxide is reported to activate proMMP-9 by S-nitrosylation.⁷⁹

A similar stepwise activation is proposed for the proteolytic activation of proMMPs. Proteinases initially attack the proteinase-susceptible bait regions in the propeptides and generate proteolytically active intermediates through destabilization of the Cys-Zn²⁺ interaction.⁶ In the second step, the final activation site is autolytically catalyzed by the active intermediate instead of the trigger proteinases, and active MMPs without propeptides are made. In many cases, the bait region sequences in the propeptide dictate which proteinases can become an activator of a particular MMP.⁶ Potential activators of proMMPs are listed in Table 8-8. Plasmin may play a major role in the activation of proMMP-3 and proMMP-10 in vivo because treatment of these proMMPs with plasmin leads to full activation in vitro.⁸⁰ ProMMP-1 activation by plasmin alone results in only about 25% of the potential MMP-1 activity, however, and full activation requires the subsequent cleavage of the Gln⁸⁰-Phe⁸¹ bond by active MMP-3, MMP-7, or MMP-10.^{6,22} MMP-3 and MMP-10 can directly activate proMMP-7,²² proMMP-8, proMMP-9,^{14,20} and proMMP-13¹¹ into fully active forms. This intermolecular activation cascade of MMPs may be important to in vivo activation of proMMPs.

Intracellular Activation

Because proMT-MMPs, proMMP-23, proMMP-11, and proMMP-28 have basic motifs containing an RXKR sequence at the end of the propeptide domains, proprotein convertases such as furin, a processing enzyme in the *trans*-Golgi apparatus, are considered to activate these proMMPs intracellularly (see Figure 8-2). Intracellular activation of proMMP-11 and proMMP-14 (proMT1-MMP) by furin is shown.^{26,81} After the activation, MMP-11 is secreted from the cells and MMP-14 is expressed on the cell membranes. Because other proMT-MMPs, proMMP-23, and proMMP-28 also have the motif, furin is presumably responsible for the intracellular activation of these proMMPs.

Pericellular Activation

ProMMP-2 is unique in that it is activated pericellularly by MMP-14 (MT1-MMP), MMP-15 (MT2-MMP), MMP-16

Figure 8-2 Activation mechanisms of proMMPs. Most secreted-type proMMPs such as proMMP-3 are activated extracellularly by many proteinases (extracellular activation). Furin-activated secreted proMMPs including proMMP-11 and proMT-MMPs such as proMT1-MMP (proMMP-14) are intracellularly activated through removal of the propeptides (arrowheads) by the action of proprotein convertases such as furin (intracellular activation). ProMMP-2 is activated on the cell membrane by MT1-MMP (MMP-14); this activation requires the trimolecular complex of MT1-MMP/TIMP-2/proMMP-2 and dimerization of MT1-MMP (pericellular activation). Ct, C-terminal domain of TIMP-2; F, furin recognition site.

(MT3-MMP), MMP-24 (MT5-MMP), and MMP-25 (MT6-MMP), but not by ordinary MMP-activatable endopeptidases.¹³ MMP-17 (MT4-MMP) does not activate proMMP-2. This pericellular activation has been extensively studied with MMP-14 and found to occur in a two-step manner. MMP-14 cleaves the Asn³⁷-Leu³⁸ bond in the propeptide of proMMP-2, generating an intermediate form that is converted to a fully activated enzyme by an intermolecular autocatalytic mechanism.⁷⁰ TIMP-2 is essential to the efficient pericellular activation of proMMP-2 by MMP-14. The

N-terminal inhibitor and C-terminal tail domains of TIMP-2 bind to the catalytic domain of MMP-14 and the C-terminal hemopexin-like domain of proMMP-2, forming a trimolecular complex of MMP-14/TIMP-2/proMMP-2 on the cell membranes (see Figure 8-2). Capturing proMMP-2 by the trimolecular complex formation on the cell membranes assists proMMP-2 activation by increasing a local concentration of proMMP-2 and presenting it to the near, noninhibited MMP-14.⁷³ Dimerization of MMP-14 through an interaction of the C-terminal hemopexin-like domain is required for the efficient activation of proMMP-2 by MMP-14.⁸² MMP-14 initiates proMMP-2 activation by attacking a part of the proMMP-2 propeptide, and another already activated MMP-2 finally activates proMMP-2 by removing a residual portion of the propeptide. Integrins such as $\alpha v \beta 3$ may be involved in the process as an additional receptor for transferring activated MMP-2 to the integrin.⁸³ MMP-15, MMP-16, or MMP-24 can activate proMMP-2 in the transfected cells,^{37-39,84} but the activation mechanisms for these MT-MMPs are not well understood. MMP-14 also activates proMMP-13 on the cell surface,⁸⁵ and this activation does not seem to require TIMP-2.⁸⁶

Pericellular activation of proMMP-7 has been discovered through screening proMMP-7-binding molecules by a yeast two-hybrid system.⁸⁷ ProMMP-7 is captured on the cell membrane by the interaction of the proMMP-7 propeptide with the C-terminal extracellular loop of CD151, a member of the transmembrane 4 superfamily, and is pericellularly activated.⁸⁷ This new pericellular activation of proMMP-7 requires a substrate of MMP-7. Integrins such as $\alpha 3 \beta 1$ and $\alpha 6 \beta 4$, α chains of which interact with CD151, also may be involved in the activation. Although the precise molecular mechanisms of this pericellular activation system, including the activator itself, are still unclear, proMMP-7 and CD151

Table 8-8 Activators of Pro-Matrix Metalloproteinases

ProMMP	Activator
ProMMP-1	Trypsin (partial); plasmin (partial); plasma kallikrein (partial); chymase (partial); MMP-3; MMP-7; MMP-10; MMP-11
ProMMP-2	MT1-MMP; MT2-MMP; MT3-MMP; MT5-MMP
ProMMP-3	Plasmin; plasma kallikrein; trypsin; tryptase; chymase; cathepsin G; chymotrypsin; neutrophil elastase; thermolysin

are overexpressed in osteoarthritic chondrocytes, and proMMP-7 is activated by the interaction with CD151 in articular cartilage of osteoarthritis.⁸⁸

Pericellular Docking of Matrix Metalloproteinases

Discovery of membrane-anchored MMPs (i.e., MT1-, MT2-, MT3-, MT4-, MT5-, MT6-MMPs and MMP-23) and subsequent studies of proMMP-2 activation by MMP-14 (MT1-MMP) have established pericellular actions of these MMPs including MMP-2. Secreted MMPs were originally thought to digest ECM macromolecules extracellularly after the activation, but more recent studies have indicated the possibility that they also may function on the cell membranes through their cell surface docking.^{74,89,90} Besides the proMMP-2/TIMP-2/MMP-14 system, several secreted MMPs are reported to interact with cell membrane proteins, which include α_2 chains of integrin $\alpha_2\beta_1$ and CD147 (EMMPRIN) for MMP-1,⁹¹ $\alpha_v\beta_3$ integrin and caveolin-1 for MMP-2,^{83,92} CD44 heparan sulfate proteoglycan and cholesterol sulfate on the cell surface for MMP-7,^{93,94} and CD44 for MMP-9.⁹⁵ Because all of these cell membrane proteins bind to active forms of the MMPs, their proteolytic activities can be used on the cell surfaces to digest ECM and non-ECM molecules located close to the cell membranes. The importance of pericellular docking of secreted MMPs in arthritic tissues should be shown by further work.

JOINT DESTRUCTION AND PROTEINASES

Degradation of Extracellular Matrix in Articular Cartilage

In most joint diseases such as rheumatoid arthritis and osteoarthritis, articular cartilage is the major target tissue for destruction, and excessive degradation of cartilage ECM by proteinases is a key process in the destruction. Histologically, depletion of proteoglycans from articular cartilage (degradation of proteoglycans) is a common initial change in these joint diseases, and subsequently collagen fibrils are degraded, leading to fibrillation and laceration secondary to destruction of the arcade structures of collagen fibrils in the articular cartilage (Figure 8-3).

Aggrecan, a major proteoglycan in cartilage, is susceptible to degradation by many proteinases including MMPs, ADAMTS species, neutrophil elastase, cathepsin G, and cathepsin B. Because most of these proteinases mainly cleave the peptide bonds located in the interglobular G1-G2 domain, the major glycosaminoglycan-bearing aggrecan fragments are detached from the hyaluronan attachment site (G1 domain) after the cleavage and released from the cartilage matrix. The two major aggrecan fragments with the N-terminal sequences starting from Phe³⁴² or Ala³⁷⁴ of the core protein are detected in joint fluids from patients with various inflammatory arthritides and osteoarthritis.⁹⁶ Many MMPs including MMP-1, MMP-2, MMP-3, MMP-7, MMP-8, MMP-9, MMP-13, and MMP-14 preferentially cleave the Asn³⁴¹-Phe³⁴² bond (the MMP site).²¹ ADAMTS species including ADAMTS1,⁴⁹ ADAMTS4,⁵⁰ ADAMTS5,⁵¹ ADAMTS8, ADAMTS9, and ADAMTS15

Figure 8-3 Structure of normal articular cartilage and its destruction by proteinases in rheumatoid arthritis. Normal articular cartilage is divided into four zones (I, II, III, and IV). Collagen fibrils are aligned parallel to the articular surface in the superficial zone, and they blend with radial fibers and form plates or sheets sweeping vertically through the middle zone, showing arcade structures that originate from the calcified zone (IV). In rheumatoid arthritis, synovial tissue cells and inflammatory cells produce various proteinases, most of which are secreted into synovial fluid. These proteinases in synovial fluid attack the surface of the articular cartilage from the synovial fluid (a). At the periphery of the articular surface, proteolytic synovium degrades cartilage by direct contact, and pannus tissue covers and invades cartilage (b). Chondrocytes, which secrete proteinases by stimulation with various cytokines and growth factors, also are implicated in cartilage destruction (c).

clip the Glu³⁷³-Ala³⁷⁴ bond (the aggrecanase site) in addition to other sites in the G2-G3 domains. Members of the MMP and ADAMTS families may play central roles in the aggrecan degradation in arthritides. On the basis of the data that synthetic MMP inhibitors do not efficiently prevent aggrecan degradation in articular cartilage, the focus has been on ADAMTS species as aggrecan-degrading proteinases in arthritides. It is not settled, however, whether MMP and ADAMTS species play differential or complementary roles in the aggrecan degradation. Decorin, a leucine-rich repeat proteoglycan, also is digested by MMP-2, MMP-3, and MMP-7⁹⁷ and ADAMTS4.⁵⁴ Information about proteinases responsible for the degradation of other proteoglycans including fibromodulin, lumican, biglycan, PRELP (arginine-rich end leucine-rich repeat protein), chondroadherin, and syndecan present in articular cartilage is limited, although fibromodulin is cleaved by C-terminus-truncated ADAMTS4.⁵⁴

Fibrillar interstitial collagens (i.e., types I, II, and III collagens) are extremely resistant to most proteinases because of their triple-helical structures. In general, classic collagenases including MMP-1, MMP-8, and MMP-13 are responsible for degradation of these collagens. Among them, MMP-13 may be most important for the degradation of cartilage collagen because it preferentially digests type II collagen.¹¹ MMP-14 degrades types I, II, and III collagens.⁴⁰ Type III collagen also is susceptible to degradation by MMP-3,⁸⁰ MMP-9,¹⁴ MMP-16,⁴² and neutrophil elastase. Cleavage

of the telopeptides by the telopeptidase activity of MMP-3,¹⁹ MMP-9,¹⁴ neutrophil elastase, cathepsin G, and cysteine proteinase cathepsins is important for depolymerization of the cross-linked collagens. When the collagen molecules are cleaved, the helical structures are unwound at 37° C (i.e., body temperature) and become denatured into gelatins, which are digested into smaller peptides by gelatinases (MMP-2 and MMP-9)^{13,14} and other nonspecific tissue proteinases. Type V collagen is readily digested by MMP-2¹³ and MMP-9.¹⁴ In contrast, type VI collagen is resistant to most MMPs including MMP-1, MMP-2, MMP-3, MMP-7, MMP-9, MMP-10, and MMP-14 but is susceptible to neutrophil elastase, cathepsin G, chymase, and tryptase.⁷ Type IX collagen is degraded by MMP-3.¹⁹ Type X collagen is susceptible to MMP-1 and MMP-2, and type XI collagen is degraded by MMP-2.

Fibronectin is degraded by many MMPs including MMP-2, MMP-3, MMP-7, MMP-10, MMP-11, MMP-13, MMP-19, MMP-14, MMP-15, MMP-16, and other serine proteinases. Link protein also is susceptible to many proteinases such as MMP-1, MMP-2, MMP-3, MMP-7, MMP-8, MMP-9, MMP-10, neutrophil elastase, and cathepsin G. COMP is digested by MMP-19 and MMP-20.³⁵ Proteinases capable of digesting cartilage matrix protein and cartilage intermediate layer protein are unknown, however.

Cartilage Destruction by Proteinases in Rheumatoid Arthritis

Articular cartilage in rheumatoid arthritis is destroyed by proteinases in three pathways: (1) destruction from surfaces of articular cartilage by proteinases present in synovial fluid, (2) destruction through direct contact of proteolytic synovium or pannus tissue or both to articular cartilage, and (3) intrinsic destruction by proteinases derived from chondrocytes (see Figure 8-3).

Rheumatoid arthritis is characterized by chronic proliferative synovitis, which shows hyperplasia of the synovial lining cells, inflammatory cell infiltration, and angiogenesis in the sublining cell layer. Hyperplastic synovial lining cells overproduce MMP-1, MMP-3, MMP-9, MMP-14, and ADAMTS4 and TIMP-1 and TIMP-3.⁹⁸⁻¹⁰⁰ Sublining fibroblasts produce MMP-2 and TIMP-2. Polymorphonuclear leukocytes infiltrated in the synovium and joint cavity contain MMP-8 in the specific granules and MMP-9 and neutrophil elastase, cathepsin G, and proteinase 3 in the azurophil granules. They are released from cells during phagocytosis of tissue debris and immune complexes. Other inflammatory cells in the synovium include macrophages, lymphocytes, and mast cells. Macrophages produce MMP-1, MMP-9, TIMP-1, and TIMP-2. uPA and cathepsins B, L, and D also are secreted from activated macrophages. T lymphocytes in the synovium synthesize MMP-9. Chymase and tryptase are degranulated from mast cells in response to activation by immune complexes. Endothelial cells express many MMPs including MMP-1, MMP-2, MMP-3, MMP-9, and MMP-14; tPA; and their inhibitors. These proteinases may be involved in tissue remodeling during angiogenesis in the synovium instead of cartilage destruction.

All of these proteinases and inhibitors produced by synovial tissue cells and inflammatory cells seem to be secreted into the synovial fluid and attack the surfaces of articular

cartilage when active proteinases overwhelm inhibitors. MMP-1, MMP-2, MMP-3, MMP-8, MMP-9, TIMP-1, and TIMP-2 are detectable in rheumatoid synovial fluids, and the molar ratios of MMPs to TIMPs correlate with metalloproteinase activity, which is detectable in rheumatoid synovial fluids.¹⁰¹ MMPs are thought to be in favor of proteinase in rheumatoid synovial fluids. The cartilage in the central part of the articular surface shows surface irregularity (fibrillation) and proteoglycan depletion without being covered by pannus tissue even in the early stage of rheumatoid arthritis (Figure 8-4). This cartilage degradation may be ascribed to the proteolytic damage by the action of the proteinases present in synovial fluid (see Figure 8-3). Among the MMPs detected in synovial fluids, MMP-3 has the highest concentration and serum MMP-3 can be used to monitor the activity of rheumatoid synovitis.¹⁰²⁻¹⁰⁴

Articular cartilage at the margins of the articular surface, to which synovial tissue can directly attach, is progressively degraded even in the early stage (see Figure 8-4). Because rheumatoid synovial lining cells exhibit strong gelatinolytic activity, which is probably generated through activation of proMMP-2 by the action of MMP-14,⁹⁸ direct contact of the proteolytically active synovial tissue to articular cartilage is a destruction pathway of the cartilage (see Figure 8-3). Although rheumatoid synovium contains high concentrations of active proteinases, the synovium can avoid the attack by MMPs because type VI collagen, a major component in the lining cell layer,¹⁰⁵ is resistant to the activities of MMP-1, MMP-2, MMP-3, and MMP-14.^{40,105} Pannus tissue is a connective tissue growing from the marginal transitional zone on the surface of the partially degraded articular cartilage. It is unknown whether pannus tissue formation is a sign of active destruction or repair of the articular cartilage, but the balance of data favors the

Figure 8-4 Destruction of articular cartilage of the proximal interphalangeal joint obtained by autopsy from an early-stage rheumatoid patient. Articular cartilage shows fibrillation and proteoglycan depletion at the central part of the articular surface (*small arrows*) and marked destruction at the marginal area, which contacts synovium (*large arrows*). Alcian blue staining for proteoglycans.

former. Immunolocalization of MMP-1 and phagocytosis of collagen fibrils by pannus cells at sites of pannus-cartilage junction may suggest a role of the tissue in the cartilage destruction.

In addition to the extrinsic pathway for the cartilage damage, cartilage may be destroyed by proteinases derived from chondrocytes (see Figure 8-3). Chondrocytes under stimulation are capable of expressing various proteinases including MMP-1, MMP-2, MMP-3, MMP-7, MMP-9, MMP-13, MMP-14, MMP-16, ADAM9, ADAM10, ADAM17, ADAMTS4, and other classes of proteinases. In rheumatoid arthritic cartilage, MMP-1, MMP-2, MMP-3, MMP-7, MMP-9, MMP-13, and MMP-14 are expressed in the chondrocytes located in the proteoglycan-depleted zone. When large areas of the cartilage surface are ulcerated after degradation of cartilage ECM, death of chondrocytes occurs, leading to further progressive cartilage destruction.

Bone Resorption in Rheumatoid Arthritis

Bone is resorbed by osteoclasts even in the early stage of rheumatoid arthritis. This is commonly observed at the bare zone, where pannus-like granulation tissue invades the bone marrow and destroys subchondral bone. Activated osteoclasts attach to only mineralized bone matrix, and this cell-matrix contact is carried out between $\alpha v \beta 3$ integrin of osteoclasts and Arg-Gly-Asp (RGD) sequence of osteopontin in the matrix. ECM degradation of the mineralized bone is possible only after demineralization of the bone matrix by proton secreted by osteoclasts because proteinases cannot permeate the matrix components in the mineralized tissues. Matrix degradation by osteoclasts is performed in the sub-osteoclastic compartments, which have acidic (pH 4 to 5) and hypercalcemic (40 to 50 mM Ca^{2+}) conditions.¹⁰⁶

The major component of the ECM proteins in mature bone is insoluble, highly cross-linked type I collagen, although type III and V collagens also are present. Other minor components in bone matrix are leucine-rich repeat proteoglycans (decorin and biglycan) and glycoproteins such as osteopontin, osteonectin (SPARC), osteocalcin (bone Gla-protein), and thrombospondin. Among collagenolytic cysteine proteinases including cathepsins B, K, L, and S, cathepsin K is considered to be most important for bone resorption because of its collagenolytic activity with a broad pH optimum and selective expression in osteoclasts and giant cells of giant cell tumors. Mutations of human cathepsin K are responsible for pyknodysostosis, an autosomal recessive osteochondrodysplasia characterized by osteopetrosis and short stature.¹⁰⁷ Cathepsin K-deficient mice have a similar phenotype. Despite the importance of cathepsin K in bone resorption, osteoclastic bone resorption cannot be completely inhibited by cysteine proteinase inhibitors; it is inhibited to a similar degree by MMP inhibitors.¹⁰⁶ MMP-9 is highly expressed in osteoclasts in normal and rheumatoid bones¹⁰⁸ and giant cells of giant cell tumors. MMP-9 has telopeptidase activity against soluble and insoluble type I collagen and strong gelatinolytic activity.^{14,108} ProMMP-9 is activated by acid exposure, and when activated, it is proteolytically active under acidic and hypercalcemic conditions.¹⁰⁸ MMP-9-deficient mice show a transient disturbance of growth plate development. Cathepsin K and MMP-9 may be involved in bone resorption in rheumatoid

arthritis. Although MMP-14 is reportedly expressed in osteoclasts in rheumatoid arthritis,¹⁰⁹ evidence of the direct involvement in osteoclastic bone resorption is limited. A more recent study shows that prostate cancer-induced osteolysis is carried out via the solubilization of receptor activator of nuclear factor κB ligand by the action of MMP-7 expressed by osteoclasts in rodents.¹¹⁰ No data are available, however, for the involvement of MMP-7 in the osteoclastic bone resorption in rheumatoid arthritis.

Cartilage Destruction by Proteinases in Osteoarthritis

In osteoarthritis, no prominent inflammatory changes occur in the synovium during early stages of the disease, but elevated production of enzymes by the chondrocytes themselves contributes to the breakdown of cartilage. Many MMPs including MMP-1,¹¹¹ MMP-2,^{78,112} MMP-3,¹¹³ MMP-7,¹¹⁴ MMP-8,¹¹¹ MMP-9,¹¹² MMP-13,^{10,111} and MMP-14⁷⁸ are expressed in osteoarthritic cartilage. MMP-3, MMP-7, and MMP-14 are immunolocalized to chondrocytes in the proteoglycan-depleted zone of osteoarthritic cartilage, and the levels of their staining correlate directly with the histologic Mankin score.^{78,113,114} Among the classic collagenolytic MMPs (i.e., MMP-1, MMP-8, and MMP-13), MMP-13 may be most important for degradation of the cartilage collagen because of preferential digestion of type II collagen over type I and III collagens.^{10,11} Because MMP-14 efficiently activates proMMP-2 within the osteoarthritic cartilage,⁷⁸ and it can activate proMMP-13,⁸⁶ MMP-14 may play a key role in cartilage degradation through activation of proMMP-2 and proMMP-13 and its own proteolytic activity against cartilage ECM. Considering intermolecular activation cascade for proMMPs by active MMPs, another key MMP in osteoarthritic cartilage tissue is MMP-3, which can activate proMMP-1, proMMP-7, proMMP-8, proMMP-9, and proMMP-13. MMP-3 not only digests many cartilage ECM components such as aggrecan, type IX collagen, and link protein but also activates those proMMPs. ProMMP-7 is activated pericellularly after being anchored via the complex formation with CD151 in osteoarthritic chondrocytes.⁸⁸ Because CD151 immunoreactivity directly correlates with the Mankin score and the degree of chondrocyte cloning, and MMP-7 not only digests cartilage ECM but also sheds precursors of growth factors such as HB-EGF, MMP-7 may be involved in cartilage destruction or chondrocyte cloning or both.⁸⁸

Other proteinases implicated in cartilage destruction in osteoarthritis are members of the ADAMTS family. Chondrocytes are known to express ADAMTS1, ADAMTS4, and ADAMTS5, the latter two of which most efficiently degrade aggrecan. On the basis of the data that the cartilage destruction in experimental osteoarthritis is prevented in ADAMTS5 knockout mice, but not ADAMTS4 knockout mice, ADAMTS5 is considered to play a key role in the cartilage destruction in mice.¹¹⁵ In human osteoarthritic cartilage, however, ADAMTS4 is overexpressed, whereas ADAMTS5 expression is constitutive.¹¹⁶ The expression of ADAMTS4, but not ADAMTS5, is stimulated with IL-1 and TNF in human osteoarthritic chondrocytes.¹¹⁷ The differential role of ADAMTS4 and ADAMTS5 in human osteoarthritic cartilage remains elusive. Members of the

ADAM family (i.e., ADAM10, ADAM12, ADAM15, and ADAM17) are expressed in osteoarthritic cartilage. ADAM12 may be involved in cartilage repair because ADAM12 is overexpressed by clustered chondrocytes and plays a role in chondrocyte proliferation by promoting the availability of IGF-I through cleavage of IGF-BP-5R.¹¹⁸ On the basis of the data of ADAM15 knockout mice, ADAM15 is considered to have a chondroprotective role in cartilage.¹¹⁹ RECK is overexpressed by clustered chondrocytes in human osteoarthritic cartilage and may play a role in chondrocyte cloning (cluster formation) through suppression of chondrocyte migration and promotion of chondrocyte proliferation.¹²⁰

Dendritic Cells

SHAUKAT KHAN • MERJA RUUTU •
RANJENY THOMAS • NINA BHARDWAJ

KEY POINTS

Dendritic cells (DCs) are professional antigen-presenting cells, abundant at body surfaces and within tissues, where they sense microbes and sample the environment for antigens.

Upon antigen capture, DCs migrate to lymphoid tissues, where they present processed antigens to naïve T cells and induce immunity or tolerance.

DCs must undergo a process of “maturation,” exemplified by antigen processing, induction of major histocompatibility complex (MHC) molecules, co-stimulatory molecules (CD80/86), and cytokine production to activate T cells.

Depending on the stimuli, maturation of DCs confers them with the ability to differentiate naïve T cells into T helper (Th)1, Th2, or Th17 cells, or regulatory T cells (Tregs). Maturing DCs also express cytokines that enable the activation of B cells and natural killer (NK) cells.

For antigen uptake, DCs express a variety of pattern recognition receptors (PRRs), such as Toll-like receptors (TLRs), C-type lectin receptors (CLRs), retinoic acid inducible gene I (RIG-I)-like receptors (RLRs), nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs), apoptotic cell recognition receptors (ACRs), and Fcγ receptors (FcγRs).

Two major subsets of DCs—plasmacytoid DCs (pDCs) (CD123⁺, CD45RA⁺) and conventional DC (cDCs) (CD11c⁺, CD45RO⁺)—are characterized by distinct origins, receptors, and functions. cDCs can be subdivided into additional subsets based on their location and function, such as Langerhans cells.

DCs play a critical role in the maintenance of tolerance in the thymus and in the periphery. Constitutive ablation of DCs breaks self-tolerance of CD4⁺ T cells and results in autoimmunity.

Dendritic cells (DCs) are potent antigen-presenting cells (APCs) implicated in the induction of immunity and in the maintenance of tolerance. DCs represent a sparsely distributed population of bone marrow–derived mononuclear cells that are found in most tissues of the body. In the immature state, they are primed to capture antigens through expression of several receptors that enable recognition and acquisition of foreign and self-antigens.¹ Upon encountering pathogen-associated molecular patterns (PAMPs) or danger-associated molecular patterns (DAMPs), DCs undergo a process of “maturation,” involving changes in the DC phenotype, antigen acquisition capacity, migration, and an ability to traffic to draining lymph nodes, where they prime humoral and cellular immune responses.¹ Under steady state conditions, DCs play an active role in maintaining tolerance to self-antigens. Although most autoimmune cells are deleted in the thymus through a process of negative selection, others must be tolerized through active and sustained mechanisms.

This chapter summarizes our current understanding of the functions of DCs, their potential role in autoimmunity, and their use as immunotherapeutic agents for autoimmune diseases such as rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE).

DENDRITIC CELL SUBSETS

No single cell surface antigen uniquely recognizes all DC subsets, unlike B cells and T cells, which can be recognized by expression of surface immunoglobulin or T cell receptors, respectively. This is due to the heterogeneity of DCs, which include several distinct subpopulations, such as conventional DCs (cDCs) and plasmacytoid DCs (pDCs), producers of interleukin (IL)-12 and interferon (IFN)-α, respectively. This division of DCs into cDC and pDC subsets is likely to present an oversimplified view of DC heterogeneity. The heterogeneous nature of DCs also presents a challenge for identifying developmental lineages; however, their heterogeneity is probably a reflection of the specialized functional role of DC subsets in different tissues and antigenic challenges.

In this chapter, we concentrate on human DCs with little additional reference to murine models. Readers are encouraged to seek additional information in several comprehensive reviews.²⁻⁶

Conventional DCs (cDCs)

Conventional DCs, or myeloid DCs, herein referred to as cDCs, comprise different subsets based on location, function, and phenotype (Table 9-1). cDCs are APCs with high phagocytic activity as immature cells and high antigen presentation as mature cells with the ability to secrete large quantities of cytokines.² They express myeloid markers (CD11c, CD33, CD13) and high levels of major histocompatibility complex (MHC)-I, MHC-II, and co-stimulatory molecules (CD80, CD86). cDCs are present in the circulatory system and can be found in virtually every peripheral tissue, as well as in lymphoid organs. They are highly migratory cells that upon maturation express chemokine receptors, such as CCR7, allowing them to move from tissues to the subcapsular sinus and the T cell zone of lymphoid organs via afferent lymphatic and high endothelial venules. In lymph nodes, cDCs can regulate T cell responses both in steady state (to induce tolerance or anergy) and during infection (Figure 9-1). They are potent producers of IL-12 and prime naïve T cells toward a T helper (Th)1 profile.

cDCs can be subcategorized into three components according to their localization: (1) peripheral tissue resident, such as skin; (2) secondary lymphoid organ resident; and (3) circulating blood cDC.⁵ Here we briefly describe some of the cDC subsets based on their localization. Understanding of DC subsets is critical not only in any future development of vaccines or treatments but also in understanding of autoimmune disease pathogenesis because each subset induces distinct responses.

Tissue Resident cDCs

In skin, three DC subsets can be identified: The epidermis contains only Langerhans cells (LCs), and the dermis contains CD1a⁺ and CD14⁺ DCs.

Langerhans Cells (LCs). LCs are located in the epidermis and have distinct markers, including CD1a and the C-type lectin receptor (CLR) langerin (CD207); LCs contain large granules called *Birbeck granules*. One of the pathways utilized by LCs to deliver antigen to T cells runs through langerin, which delivers antigen to Birbeck granules to be presented in a CD1a-restricted manner.⁷ The CD1 family of molecules is associated with presentation of glycolipids, and CD1a antigen presentation is independent of endosomal localization and acidification. LCs constitutively express E-cadherin, a homotypic adhesion molecule that anchors LCs to neighboring keratinocytes.⁸ Under steady state conditions, immature LCs migrate to the lymph node and induce T cell tolerance. During inflammation, migratory LCs upregulate MHC class II molecules, co-stimulatory molecules such as CD40, and CCR7, while expression of E-cadherin is downregulated, which facilitates LC disengagement from neighboring keratinocytes.⁸ In mice, LCs have been shown to be self-renewing in situ and are not replaced by bone marrow transfer in the steady state; data supporting their role as immunogenic APCs are conflicting.⁸

Dermal DCs. The CD14⁺ dermal DCs express a broad spectrum of C-type lectins, including DEC-205 (see Table 9-1). They have been shown to induce the differentiation of CD40-activated B cells into immunoglobulin (Ig) M-producing plasma cells through cytokine secretion (IL-12 and IL-6) and through direct cell-cell interaction.⁹ CD14⁺ DCs promote antibody responses through skewing of CD4⁺ T cells into T follicular helper (Tfh) cells, which induce naïve B cells to switch isotype and secrete large quantities of immunoglobulins.⁹

CD1a⁺ dermal DCs express blood DC antigen 1 (BDCA-1) and are present in the upper layer of the dermis. Phenotypically they are similar to LCs but lack expression of langerin and E-cadherin.⁵ On stimulation, CD1a⁺ DCs produce IL-15 and few proinflammatory cytokines, except IL-8, and chemokines also expressed by dermal CD14⁺ DCs.⁵ They can induce Th2 responses and cytotoxic T lymphocyte (CTL) responses, however with less potency than LCs or CD14⁺ DCs.

Table 9-1 Dendritic Cell (DC) Subsets

Subset	Conventional DCs (cDCs)					Plasmacytoid DCs (pDCs)
	Langerhans Cells	Dermal DCs		Blood DCs		
		CD14 ⁺	CD1a ⁺	BDCA1 ⁺	BDCA3 ⁺	
TLR	TLR1, 2, 3, 6, 10	TLR2, 4, 5, 6, 8, 10	TLR2, 3, 4, 5	TLR1, 2, 3, 4, 5, 6, 7, 8, 10	TLR2, 3, 8	TLR7, 9
C-type lectins	Langerin	DC-SIGN, DEC-205, LOX-1, CLEC-6, Dectin-1, DCIR	Langerin, DEC-205	DEC-205, DCIR, BDCA-1	CLEC9A (DNGR-1), BDCA-3	BDCA-2
Cytokine production	IL-12, IL-15, IL-23, IL-6, TNF, IL-1β					IFN-α, IFN-β, IL-6, TNF
Function	Priming of antigen-specific CD4 ⁺ , CD8 ⁺ T cells, B cells; NK cell activation via IL-12; differentiation of T helper cells					Induction of Tregs; induction of plasma cells; NK cell activation via type I IFN-α

BDCA, blood DC antigen; CLEC, C-type lectin; DCIR, dendritic cell inhibitory receptor; DC-SIGN, DC-specific ICAM-3 grabbing nonintegrin; DEC, dendritic and epithelial cells; DNGR, DC NK lectin group receptor; ICAM, intercellular adhesion molecule; IFN, interferon; IL, interleukin; LOX-1, lectin-like oxidized LDL receptor-1; NK, natural killer; TLR, Toll-like receptor; TNF, tumor necrosis factor.

Figure 9-1 Dendritic cell-mediated modulation of adaptive immunity. Immature dendritic cells (DCs) are activated through triggering of Toll-like receptors (TLRs), nucleotide-binding oligomerization domain (NOD) proteins, or retinoic acid inducible gene I (RIG-I)-like receptors by pathogen- or host-associated molecular patterns (“tissue factors”). DC activation leads to maturation and migration to secondary lymphoid tissues, where they interact and activate naïve T cells. Skewing of T cell responses is determined by DC-derived signals, including levels of antigen presentation (*Signal 1*), display of co-stimulatory molecules (*Signal 2*), and cytokines (*Signal 3*). *Signal 1* is mediated by upregulation of major histocompatibility complex (MHC) II-peptide complexes and interaction with T cell receptor (TCR). *Signal 2* is mediated by engagement of CD80 and CD86 with CD28 on T cells. Finally, *Signal 3* is provided by cytokines produced by DCs, including interleukin (IL)-12, IL-23, tumor necrosis factor (TNF), IL-6, IL-1β, or type I interferon (IFN). Skewing of the T helper (Th)1 cell is mediated predominantly by IL-12. Epithelial cells, mast cells, and basophils release thymic stromal lymphopoietin (TSLP), which induces OX40 ligand (OX40L) on DCs and subsequent induction of Th2 skewing. DC secretion of IL-6, upon TLR stimulation in the presence of transforming growth factor (TGF)-β, induces Th17 differentiation. IL-23 is needed for stabilization of Th17 cells. In the absence of proinflammatory cytokines, TGF-β can induce regulatory T cell (Treg) differentiation. CD40-CD40L interaction between DCs and CD4⁺ T cells “licenses” the DC for CD8⁺ T cell priming. This so-called T cell feedback signal is crucial for DCs to induce cytotoxic T cells (CTLs) and generate effective CD8⁺ memory cells.

Lymphoid Tissue DCs

DC subsets can be identified in tonsils, lymph nodes, and spleen.⁶ Intestinal DCs can be found in the lamina propria, Peyer’s patches, solitary lymphoid tissue, and mesenteric lymph nodes, where they process and sample luminal and self-antigens for presentation.¹⁰ Here we briefly describe BDCA-3⁺ and CD103⁺ DCs.

BDCA-3⁺ DCs. BDCA-3⁺ (CD141) DCs are considered to be the counterpart of mouse CD8α⁺ DCs found in lymph nodes, based on functional and phenotypic analyses.^{11–13} BDCA-3⁺ DCs are found in lymph nodes, tonsils, bone marrow, and spleen, where they localize to T cell areas, but they are the rarest population of cDCs in blood. They express Toll-like receptor (TLR)3 and TLR8, and CLEC9A (DC natural killer [NK] lectin group receptor-1 [DNKR-1]), a C-type lectin that can act as a sensor of necrotic cells.¹¹ These DCs phagocytose dead cells, process captured antigens, and cross-present them to CD8⁺ T cells. Because cross-presentation is essential for eradication of cancers, viruses, and other pathogens, BDCA-3⁺ DC cells present a promising target in vaccination strategies.¹⁴ The chemokine receptor XCR1 also seems to be selectively expressed by BDCA-3⁺ DCs.¹² Activated NK cells and CD8⁺ T cells produce XCL1, a ligand for XCR1, at the site

of infection and may serve as a signal for recruitment of BDCA-3⁺ DCs.¹⁵ On TLR stimulation, BDCA-3⁺ DCs produce IL-12 and IFN-β.¹⁴

CD103⁺ DCs. CD103⁺ DCs reside in the intestinal lymph node and efficiently induce expression of gut homing receptors CCR9 and α4β7 by responding T cells and B cells through a retinoic acid receptor-dependent mechanism.¹⁰ CD103⁺ DCs induce generation of regulatory T cells (Tregs) from naïve CD4⁺ T cells mediated through retinoic acid and transforming growth factor (TGF)-β.¹⁶ In Crohn’s disease, CD103⁺ DCs maintain their ability to induce CCR9 expression by T cells, similar to healthy control DCs in small intestine¹⁰; however, it remains to be determined whether they maintain their tolerogenic phenotype in Crohn’s disease.

Circulating DCs

Blood contains both cDCs and pDCs. cDCs migrate first to inflammatory sites and then into secondary lymphoid tissue through afferent lymph. The physiologic roles of circulating blood cDCs might include surveillance for pathogens in circulation and tissue migration to replenish DCs or recruitment in inflammatory settings. cDCs in blood can be

further subdivided into BDCA-1 (CD1c), CD16⁺, and BDCA-3⁺ populations. Monocytes have been shown to differentiate into dendritic cells in vitro and as well as in vivo in mice.

BDCA-1⁺ (CD1c) DCs. BDCA-1⁺ DCs originate from bone marrow. They circulate in the blood and migrate to secondary lymphoid organs and peripheral tissues, such as spleen and tonsil, as resting interstitial DCs.⁶ They are hypothesized to be similar to mouse CD8 α ⁺ DCs. BDCA-1⁺ DCs have a limited ability to produce IL-12 and CXCL10 (IFN-induced protein 10 [IP-10]) but produce IL-8, a chemoattractant for granulocytes, monocytes, and lymphocytes after stimulation with poly(I:C), a synthetic double-stranded RNA.^{13,17} They can also produce IL-1 β upon poly(I:C) stimulation, which can be mediated through the retinoic acid inducible gene I (RIG-I), rather than TLR3.¹³ Mouse CD8 α ⁺ DCs selectively express RIG-I.¹⁸ Similar to their mouse counterpart, they have the capacity to present antigens to CD4⁺ T cells but limited ability to cross-present.¹³

Monocyte-Derived Dendritic Cells (moDCs). Monocytes are precursors to macrophages and can differentiate into DCs (moDCs). In the presence of granulocyte-macrophage colony-stimulating factor (GM-CSF) and IL-4, monocytes acquire dendritic cell morphology, produce inflammatory cytokines, and skew naïve T cell responses in vitro. Although moDCs have not been identified in humans or mice in steady state, recent studies show that in mice, lipopolysaccharide (LPS) or LPS-expressing bacteria can mediate differentiation of monocytes to moDCs.¹⁹ These moDCs acquire DC morphology, localize to the T cell area via CCR7, and have similar antigen-presentation capacity as classic DCs, including cross-presentation.¹⁹ Hence, blood monocytes can be a reservoir of DCs in response to inflammatory situations.

Plasmacytoid DCs (pDCs)

pDCs have high capacity for type I IFN production. pDCs are found in peripheral blood, thymus, and many lymphoid tissues. pDCs display distinct plasma cell morphology, contain abundant endoplasmic reticulum, and express CD4 and high levels of IL-3 α R (CD123) but lack myeloid antigens, including CD11c, and most lineage markers. pDCs secrete high amounts of IFN- α upon viral infection but no IL-12, and although they are primed to capture virus (e.g., flu), they generally display poor antigen capture and presentation capacity. Upon activation, pDCs show similar characteristics to cDCs (e.g., dendritic morphology, high expression of MHC class II molecules) but a limited capacity to prime naïve T cells.²⁰ pDCs can prime naïve T cells toward the Th1 profile in IFN- α -dependent and IL-12-independent pathways upon viral/TLR stimulation²¹ but can also induce Tregs in an indoleamine-2,3-dioxygenase (IDO)-dependent manner, possibly to contain immune activation that is triggered, as in SLE or chronic human immunodeficiency virus (HIV) infection.²² In contrast to cDCs, pDCs contain “lymphoid” mRNA transcripts for pre-T α chains, germline IgK, and Spi-B.

pDCs have been shown to accumulate in inflamed tissues, as in early stages of psoriasis, through their expression of ChemR23 and CXCR4.²³

DENDRITIC CELL DEVELOPMENT

The developmental origin of pDCs and cDCs is still debated because pDCs and cDCs can be derived from both the common lymphoid progenitor (CLP) and the common myeloid progenitor (CMP), suggesting that pDCs and cDCs may arise during hematopoiesis from progenitors with already distinct and restricted lineage potential.²⁴ Most studies on the developmental origin of human DC subsets have used in vitro culture systems. DC precursors, similar to other hematopoietic cells, are continuously produced at a steady rate in a pathogen-independent manner from CD34⁺ hematopoietic stem cells (HSCs) within the bone marrow. DC development arises through several commitment steps in the bone marrow, from hematopoietic precursors, including macrophage/DC precursors (MDPs) and common DC precursors (CDPs). Proliferative CDPs then differentiate into DC precursors (pre-DC) and pDCs. Pre-DCs localize in bone marrow, blood, and lymphoid organs, where they give rise to immature DCs (imDCs) and mature DCs (mDCs). The pre-DC subset expresses several myeloid markers, including CD11b, CD11c, CD13, CD14, and CD33.

DC development is dependent on cytokines and specific transcription factors. Fms-like tyrosine kinase-3 ligand (flt-3-L) is critical for the development of both cDCs and pDCs. cDC differentiation is dependent on the transcription factor Ikaros and PU.1, whereas pDC development is dependent on IRF8, E2-2, and the Ets family transcription factor Spi-B, and probably PU.1.

Maturation

In their resting state, imDCs are highly specialized in antigen uptake through a variety of receptors and mechanisms. Upon encountering a pathogen or other “activation stimuli,” DCs undergo phenotypic and functional changes referred to as *maturation*; this influences their “effector” function and antigen-presenting capability (see Figure 9-1).¹

Antigen Recognition

imDCs take up and recognize and receive signals from antigens through phagocytosis, macropinocytosis, and endocytosis using Fc receptors (Fc γ receptor types I [CD64] and II [CD32]), integrins (α V β 3 or α V β 5), C-type lectins (mannose receptor DEC-205), Toll-like receptors (TLRs), nucleotide-binding oligomerization domain (NOD) proteins, and RIG-I-like receptors (discussed later). Upon antigen recognition, DCs secrete cytokines and express chemokine receptors to facilitate their migration.

Receptor Upregulation

Maturation is accompanied by increased expression of chemokine receptors, adhesion molecules, and co-stimulatory molecules that allow DC migration toward secondary lymphoid organs, facilitating interaction with T cells. DCs upregulate CCR7, which directs cells to lymphoid tissue in response to chemokines CCL19 and CCL21 expressed in the T cell areas of lymph nodes. Adhesion molecules such

as intercellular adhesion molecule-1 (ICAM-1) are also upregulated upon maturation and bind lymphocyte function-associated antigen-1 (LFA-1) on T cells.²⁵ Mature DCs are also characterized by high-level expression of MHC and T cell co-stimulatory molecules with an enhanced ability to present antigen captured in the periphery to T cells. DCs express various members of the B7 superfamily, such as B7-1 (CD80) and B7-2 (CD86), which stimulate or inhibit T cell activation, respectively, upon binding T cell CD28 or CTLA-4.²⁶ DCs constitutively express CD40, which is upregulated upon maturation and binds CD40L (CD154) expressed by activated CD4⁺ T cells, resulting in enhanced upregulation of MHC molecules and increased production of cytokines and DC survival.²⁷

Cytokine and Chemokine Secretion

cDCs predominantly produce IL-12, and pDCs IFN- α , although BDCA-3⁺ DCs can also produce IFN- β . DCs also secrete chemokines, such as regulation upon activation normal T cell expressed and presumably excreted (RANTES), macrophage inflammatory protein (MIP)-1 α , and IP-10; this enables recruitment of T cells, monocytes, NK cells, and other DCs into the local environment. Concomitantly, DCs reduce their capacity for phagocytosis, macropinocytosis, and antigen processing (discussed later). After migration to secondary lymph nodes, DCs prime naïve CD4⁺ and CD8⁺ T cells.

ANTIGEN ACQUISITION AND RECOGNITION

DCs are defined by their high capacity to capture, process, and present antigens—a prerequisite for T cell priming. DCs efficiently sample their environment through pattern recognition receptors (PRRs), which recognize PAMPs. PRRs serve as an important link between innate and adaptive immunity as they directly mature DCs and consequently dictate the production of cytokines and chemokines. PRRs can be divided, among others, into TLRs, CLRs, NOD-like receptors (NLRs), and RIG-I-like receptors (RLRs). Another set of receptors important for homeostasis of tissues includes apoptotic cell recognition receptors involved in the clearance of apoptotic cells and Fc receptors, which recognize antigen-antibody complexes.

Toll-Like Receptors (TLRs)

TLRs recognize a variety of PAMPs, such as bacterial, fungal, and nucleic acids (Table 9-2). They can be grouped into two subfamilies: TLRs expressed on cell surface (TLR1, -2, -4, -5, -6) sampling for the presence of bacterial, fungal, and protozoan components; and TLRs localized to specialized endosomal compartments (TLR3, -7, -8, and -9), detecting the presence of nucleic acids²⁸ (see Chapter 18). Although most TLRs appear to function as homodimers, TLR2 forms heterodimers with TLR1 or TLR6, and TLR4 is complexed with MD-2. DC subsets show a heterogeneous TLR expression pattern (see Table 9-2).

Activation of DCs in response to binding of TLR agonists is controlled by signaling through the Toll/IL-1 receptor (TIR) domain present in the cytoplasmic domain of TLR. Signaling downstream of the TIR domain is mediated through recruitment of myeloid differentiation factor 88 (MyD88) for all TLRs, except for TLR3. MyD88 recruitment is required for induction of nuclear factor κ B (NF κ B), which induces expression of proinflammatory cytokines such as IL-12, tumor necrosis factor (TNF), and IL-6. In pDCs, stimulation of TLR7 and TLR9 with nucleic acid induces IFN response factor 7 (IRF7) through MyD88 signaling, leading to IFN- α secretion.²⁹

In TLR3 signaling, the TIR domain of TLR3 recruits the adapter protein, TIR domain-containing adapter protein, inducing IFN- β (TRIF), which induces IRF3, leading to production of IFN- β .

TLRs play an important role in induction of autoimmunity. Under steady state conditions, DC responses to extracellular self-nucleic acids are prevented by the endosomal seclusion of nucleic acid-recognizing TLRs. However, cellular proteins and chaperones can bind and present self-nucleic acids to DCs, causing inflammation. For example, LL37 (cathelicidin), an antimicrobial peptide produced by neutrophils and keratinocytes, is found in high levels in the skin lesions of psoriasis patients. LL37 forms aggregates with self-DNA and RNA from necrotic cells, protects them from degradation, and transports them into endosomal compartments of DC. In pDCs, RNA-LL37 and DNA-LL37 complexes activate TLR7 and TLR9, respectively, and trigger the secretion of IFN- α .^{30,31} In contrast, RNA-LL37 complexes in cDCs trigger TLR8 and induce secretion of proinflammatory cytokines.³⁰ Similarly, high mobility group B1 (HMGB1) is released from necrotic cells and stimulates

Table 9-2 TLR Expressed by Dendritic Cells (DCs) and Their Ligands

Conventional DCs	Plasmacytoid DCs	Ligands
TLR1 TLR2	TLR1	Multiple triacyl lipopeptides Peptidoglycan (<i>Staphylococcus aureus</i>), lipoproteins, and lipopeptides from several bacteria Glycophosphatidylinositol anchors from <i>Trypanosoma cruzi</i>
TLR3 TLR4 TLR5 TLR6		Lipoaminomannan from <i>Mycobacterium tuberculosis</i> , zymosan (yeast) Double-stranded RNA (e.g., poly I:C) Lipopolysaccharide + MD-2, taxol, HSP60 (?), heparan sulfate (?), RSV, fibronectin Flagellin (<i>Salmonella typhimurium</i> , <i>Listeria</i>)
	TLR6	?/Undergoes dimerization with TLR2
	TLR7	Imiquimod (Aldara), R848 (resiquimod), single-stranded RNA
TLR8	TLR8	Imiquimod (Aldara), R848 (resiquimod), single-stranded RNA
	TLR9	CpG ODNs, DNA from bacteria and viruses, chromatin-IgG complexes
TLR10		?

CpG ODNs, CpG oligodeoxynucleotides; HSP, heat shock protein; Ig, immunoglobulin; RSV, respiratory syncytial virus; TLR, Toll-like receptor.

TLR2 and TLR4, mediating secretion of proinflammatory cytokines.²⁸ Heat shock proteins (HSPs), such as HSP60, HSP70, gp96, and HSP22, are also reported to be recognized by TLR2 and TLR4.²⁸

C-Type Lectin Receptors (CLRs)

DCs can also recognize, bind, and uptake specific carbohydrate moieties expressed by pathogens or self-tissues through CLRs such as the macrophage mannose receptor (MMR), DEC-205, DC-specific ICAM-3 grabbing nonintegrin (DC-SIGN), Dectin-1, Dectin-2, dendritic cell inhibitory receptor (DCIR), myeloid inhibitory C-type lectin-like receptor (MIEL, CLEC12A), CLEC9A, and BDCA-2, all of which can function as endocytic receptors to internalize antigens for degradation or antigen processing and presentation.^{32,33}

CLRs Modulate TLR Signaling

CLRs can positively and negatively modulate TLR responses. DC-SIGN recognizes mannose and fructose on pathogens such as HIV-1, measles virus, *Mycobacterium tuberculosis*, and *Candida albicans*. Modulation of TLR signaling by DC-SIGN is dependent on prior activation of NF κ B by TLR.³³ Acetylation of NF κ B p65 mediated by DC-SIGN prolongs and increases transcriptional activation from the *IL-8* and *IL-10* promoters, leading to increased cytokine secretion.³³

On the contrary, binding of Salp15, a protein antigen from the tick *Ixodes scapularis*, to DC-SIGN decreases TLR1-TLR2-dependent inflammatory cytokine production by decaying *IL-6* and *TNF* mRNA while impairing nucleosome remodeling at the *IL12a* promoter.³⁴

DC-SIGN has an essential role in DC-T cell interaction through ICAM-2 and ICAM-3, which are highly glycosylated structures. In RA synovium, the numbers of cells expressing DC-SIGN on macrophages and DC and ICAM-3 on naïve T cells were increased in the affected joints, with interaction leading to increased secretion of matrix metalloproteinases.³⁵

BDCA-2 expressed by pDC pairs with Fc ϵ R γ , which contains an immunoreceptor tyrosine-based activation motif (ITAM). Activation of BDCA-2 by antibody ligation results in downregulation of TLR9-mediated IFN- α , IFN- β , *TNF*, and *IL-6* in pDCs.³⁶ HIV gp120 was also found to inhibit TLR9-mediated IFN- α through binding of BDCA-2 on pDCs.³⁷ SLE patients have reduced expression of BDCA-2 on pDCs, and lack of negative regulation through BDCA-2 signaling may account for excessive IFN- α production on TLR stimulation.³⁸

DCIR and MIEL are the only known CLRs with immunoreceptor tyrosine-based inhibitory motifs (ITIMs) in their cytoplasmic tails, which recruits SH2-domain-containing protein tyrosine phosphatase 1 (SHP-1) or SHP-2 following antibody ligation.³³ So far no ligands have been identified for DCIR and MIEL. Activation of DCIR leads to internalization into an endosomal compartment, with TLR8 and TLR9 leading to the downregulation of TLR8-induced *TNF* and *IL-12* by cDCs, or TLR9-induced IFN- α and *TNF* production by pDCs.³³ Polymorphisms in the gene encoding DCIR have been associated with RA.³⁹ In mice,

DCIR deficiency leads to unrestricted expansion of DC numbers and development of autoimmune sialadenitis, enthesitis, and autoantibodies, including rheumatoid factor, anti-Ro and La, and antinuclear antibodies, implicating DCIR in the negative regulation of DC expansion or differentiation from bone marrow precursors.⁴⁰

Similarly, antibody-mediated cross-linking of MIEL expressed by cDCs leads to SHP-1 and SHP-2 recruitment and the suppression of TLR-induced *IL-12* production.³³

CLR Signaling Independent of TLR

Dectin-1 recognizes β -1-3 glucan expressed by fungal pathogens. Dectin-1 induces two different signaling pathways: activation by recruitment of spleen tyrosine kinase (SYK)-dependent activation of NF κ B, and activation of RAF1, leading to phosphorylation of p65, similar to DC-SIGN and TLR cross-talk. Activation and modification of NF κ B by dectin-1 leads to an increase in *IL-6*, *IL-10*, *IL-1 β* , and *IL-12p40* production and modulation of *IL12p35* and *IL-23p19* subunits, leading to bioactive *IL-12p70* and *IL-23*, respectively, resulting in generation of Th1 and Th17 cells.³³

Dectin-2, a CLR, can associate with Fc γ receptors (Fc γ Rs) similar to BDCA-2. Unlike BDCA-2, Dectin-2 induces cytokine production through Fc γ Rs. Dectin-2 recognizes fungal hyphae from *C. albicans*, *Trichophyton rubrum*, and *Microsporium audouinii* and recruits SYK to Fc γ R and induces production of *TNF* and *IL-6*.³³

CLRs Enhance Antigen Presentation

The ability of CLRs to deliver antigen to different compartments for processing has been used for targeting in vaccine studies.² It has been shown that antigen linked to DEC-205-specific antibodies resulted in enhanced antigen uptake and presentation by DCs to both CD4⁺ and CD8⁺ T cells.⁴¹ CLRs have a specific expression pattern, and some CLRs, such as DC-SIGN and Dectin-1, are expressed by several DC subsets, while expression of other CLRs is restricted to specific DC subsets (see Table 9-1). CLEC9A recognizes necrotic cells and on binding recruits Syk; in mice this activation is required for cross-presentation of necrotic cell-associated antigens by CLEC9A.⁴² BDCA-3⁺ cells in humans express CLEC9A and have been shown to cross-present viral antigens to CD8⁺ T cells and could potentially play a part in cross-presentation of self-antigen in autoimmune diseases.^{12,13}

Because CLRs are involved in immune homeostasis, their dysregulation might contribute to the predisposition to autoimmune disease. This is supported by associations of single-nucleotide polymorphisms of CLR and key components of their signaling pathways with a number of autoimmune diseases, including CLEC16A with type 1 diabetes, multiple sclerosis, juvenile rheumatoid arthritis, and inflammatory bowel disease; DCIR with rheumatoid arthritis; and CARD9 with the spondyloarthropathies, ankylosing spondylitis, and inflammatory bowel disease.⁴³⁻⁴⁷

Retinoic Acid Inducible Gene I (RIG-I)-Like Receptors (RLRs). RLRs are cytoplasmic PRRs, recognizing genomic or replication intermediate viral double-stranded RNA (dsRNA). The RLR family is composed of RIG-I,

melanoma differentiation-associated gene 5 (MDA5), and LGP2. RIG-I and MDA5 recognize short dsRNA with 5'-triphosphate ends and long dsRNA, respectively. LGP2 functions as a positive regulator of both RIG-I and MDA5.²⁸ The CARDs of RLR activate a signaling cascade, leading to expression of type I IFN genes via TRAF3 and IRF3/7. In addition, IPS-1 induces nuclear translocation of NFκB via cleavage of caspases 8 and 10.²⁸

Nucleotide-Binding Oligomerization Domain (NOD)-Like Receptors (NLRs). The NLR family of proteins consists of cytosolic, intracellular PRRs that recognize PAMPs and endogenous ligands, which induce a signaling cascade leading to activation of NFκB, or a cytoplasmic multiprotein complex known as the *inflammasome*, to produce inflammatory cytokine.⁴⁸ NLR family proteins have a trimodular structure and contain the following domains: a central nucleotide-binding NOD domain, essential for self-oligomerization, and a C-terminal domain consisting of tandem leucine-rich repeats (LRRs), essential for sensing and recognition of PRR.⁴⁸ Some proteins contain variable N-terminal domains. NOD1 contains a CARD domain, which activates transcription of proinflammatory mediators, whereas NACHT-LRR-PYD-containing protein 3 (NALP3) contains a pyrin domain (PYD), and the NLR family apoptosis inhibitory protein 5 (NAIP5) contains a baculovirus inhibitor of the apoptosis protein repeat (BIR) domain. PYD and BIR domains are components of the inflammasome that regulate caspase-1 activation, leading to the production of IL-1β.⁴⁸

NOD1 and NOD2 sense various bacterial PAMPs in the cytoplasm. Upon PAMP recognition, they undergo self-oligomerization through the CARD domain and form a complex with CARD-containing IL-1β-converting-enzyme-associated kinase (CARDIAK). This induces inflammatory cytokines through activation of NFκB and mitogen-associated protein kinases (MAPKs).⁴⁸

Pathogen infection of DCs results in the production of various cytokines of the IL-1 family, including IL-1β, IL-18, and IL-33 through TLR, NLR, and RLR. The production of these cytokines is dependent on PRR-mediated translation and transcriptional upregulation of pro-forms of these cytokines. Inflammasomes, activated by caspase-1, process cytosolic pro-IL-1β and pro-IL-18 to bioactive and secretory cytokines.⁴⁸ Inflammasomes are categorized into three types: NALP3, IL-1β-converting-enzyme-protease-activating factor (IPAF), and NALP1 inflammasome. They are activated directly or indirectly by various ligands. The NALP3 inflammasome can be activated by exogenous ligands such as viral RNA and by host endogenous ligands, including monosodium urate (MSU) and adenosine triphosphate (ATP).⁴⁸ Gout, an acute and chronic inflammation of joints, is associated with the deposition of MSU, which most likely induces inflammation through NALP3 inflammasomes.⁴⁹

NLRs are also involved in various inflammatory and autoimmune diseases. NOD2 signaling has been shown to induce Th17 responses for clearance of bacteria through the selective induction of IL-23 and IL-1, which is abrogated in DCs from Crohn's disease patients carrying a mutation in NOD2.⁵⁰ *ATG16L1*, an autophagy-related gene, was also identified in Crohn's disease. In mice, deletion of the *ATG16L1* gene leads to hyperactivation

of inflammasomes and subsequent secretion of bioactive IL-1β and IL-18, contributing to intestinal inflammation.²⁸ Therefore inappropriate responses to bacterial pathogen by DCs may contribute to the pathogenesis of Crohn's disease.

Apoptotic Cell Recognition Receptors

In addition to sampling for immunogenic antigens, DCs help in clearance of apoptotic cells in the periphery. Upon uptake of apoptotic cells or apoptotic microparticles, DCs maintain an immature phenotype and induce immunomodulatory effects. These DCs downregulate co-stimulatory molecules (CD80/86) and produce TGF-β, a cytokine necessary for differentiation of naïve T cells to Tregs.⁵¹ In contrast, uptake of necrotic cells leads to maturation and secretion of proinflammatory cytokines. Inability to clear apoptotic cells and consequent secondary necrosis have been implicated in the development of SLE. Recognition and engulfment of apoptotic cells involve multiple ligands: "eat me" signals, bridging molecules, and phagocytic receptors. One of the principal "eat me" signals is translocation of phosphatidylserine (PS) to the outer leaflet of the plasma membrane of apoptotic cells. PS can be recognized by multiple receptors, such as T cell immunoglobulin mucin (TIM-1), TIM-4, Stabilin-2, brain-specific angiogenesis inhibitor 1 (BAI1), and scavenger receptors (e.g., CD36, CD68, LOX-1). In addition, the β2-glycoprotein I (β2-GPI) receptor, αv integrins, and MER tyrosine kinase recognize PS through bridging molecules β2-glycoprotein I (β2-GPI), milk fat globular-EGF factor 8 protein (MEGF-8), and Gas6, respectively. CD36 and αvβ3 on DCs bind apoptotic cells via bridging molecule thrombospondin-1 (TSP-1); complement receptor 3 (CR3 [CD11b/CD18]) and CR4 (CD11c/CD18) via complement protein C3bi; and scavenger complex calreticulin-CD91 via surfactant proteins A (SP-A), SP-D, and C1q.⁵² CD14 and ATP-binding cassette transporter (ABC) 7 have also been implicated in recognition of apoptotic cells. In addition to providing "eat me" signals, apoptotic cells modify CD31, which prevents ingestion of viable cells.⁵²

DCs can also phagocytose necrotic cells; LOX-1 binds to heat shock proteins (HSPs) and allows cross-presentation to T cells of antigens bound to HSP.⁵³ Recently, variants of ITGAM (CD11b) were associated with SLE.⁵⁴ Polymorphisms in C1q, a complement factor, have also been linked with SLE.⁵⁵ Polymorphisms in C1q and CD11b could lead to decreased uptake of apoptotic cells and subsequent necrosis and proinflammatory responses.

A common feature of lupus patients is the presence of dying cells in both lymph nodes and inflamed tissues.⁵⁶ It is not clear whether this is due to increased cell death or innate or acquired inability to clear apoptotic cells, which normally occurs very rapidly. Increased cell death might be the consequence of oxidative stress or infection, both of which are thought to trigger autoimmune disease. Regardless of the mechanism, increased cell death increases the presence of autoantigens available for presentation by DCs. Necrotic cells attract phagocytes by secreting hyaluronic and uric acid and high mobility group box 1 protein (HMGB1), which are known inducers of inflammasome and inflammation.⁵⁷

Fc Receptors (FcRs)

Fc receptors are expressed by many immune cells and are important in regulation of immune responses to immune complexes (ICs), a complex of antigen bound to antibody and sometimes to components of the complement system. DCs express activating receptors FcγRI, FcγRIIA, FcγRIIA, and inhibitory receptor FcγRIIB.

Infected cells or pathogens coated with IgG activate FcγR-mediated clearance by antibody-dependent cell-mediated cytotoxicity (ADCC) or phagocytosis and/or indirectly through the release of cytokines. This is mediated by ITAM phosphorylation and subsequent activation of SYK and the initiation of the downstream signaling cascade resulting in cell activation.⁵⁸ In contrast, inhibitory FcγRIIB has an ITIM domain in its cytoplasmic domain, resulting in inhibition of phagocytosis and cytokine secretion.

FcγRIIB also controls IC-mediated DC maturation.⁵⁹ Low levels of IC can be identified in the serum of healthy individuals, thus FcγRIIB can prevent spontaneous DC maturation. In a small subset of well-controlled RA patients

who were able to stop disease-modifying drugs, peripheral blood monocyte-derived DCs expressed high levels of FcγRIIB, signaling through which inhibited TLR4-mediated DC activation.⁶⁰ In addition, ICs taken up by FcγRIIB are degraded inefficiently and are presented on the cell surface in native conformation, where they can interact with B cells.⁶¹ An FcγRIIB gene polymorphism has been identified in SLE and RA patients. DCs from RA patients with FcγRIIB variant showed an increase in IC-mediated inflammation in vitro.⁶²

FcγRs also alter CR3-mediated signaling of phagocytosis upon co-stimulation in vitro. Co-stimulation of CR3 with FcγRI inhibits and FcγRIIA enhances CR3-mediated phagocytosis⁶³—a potential mechanism for selective modulation of immunity.

ANTIGEN PRESENTATION

DC activation is tightly associated with processing and presentation of antigens by MHC class I and MHC class II, and lipid presentation by CD1 molecules (Figure 9-2).

Figure 9-2 Antigen presentation pathways in dendritic cells (DCs). DCs can present major histocompatibility complex (MHC) I- and MHC II-associated antigenic peptides. **A**, Antigenic peptides are generated predominantly by ubiquitination of nascent proteins, misfolded proteins, neosynthesized defective proteins, and defective ribosomal products, and subsequent degradation by the ubiquitin-proteasome system. The peptides are transported to endoplasmic reticulum (ER) through the transporter associated with antigen processing (TAP), where long peptides are further trimmed by ER aminopeptidase-1 (ERAP-1) to 8-mer or 9-mer peptides for loading onto MHC class I molecules. The trimeric complex of MHC class I heavy chains, β2 microglobulin, and peptide allows for optimal folding, glycosylation, and delivery to the cell surface. **B**, Antigens are endocytosed and retained in a phagosome before fusing with lysosomes to form phagolysosomes. Concomitant Toll-like receptor (TLR) signals induce activation of the vacuolar proton pump that enhances lysosomal acidification and antigen proteolysis in phagolysosomes. Acidification of this compartment allows optimal activity of cathepsins. Cathepsin S degrades the cytoplasmic tail of the Ii chain, leaving a short peptide from Ii, the MHC class II-associated invariant-chain peptide (CLIP), bound to the peptide-binding groove and thus protected from proteases. The CLIP is replaced in the MHC II compartment by a peptide generated through the action of endosomal proteases on endosome-trafficking proteins. Finally, loaded MHC II is transported to the cell surface. **C**, DCs can also acquire antigens exogenously and can process them for presentation on the MHC I molecule in a pathway referred to as *cross-presentation*. Cross-presentation requires peptides to gain access to cytosol, be processed by proteasome, and get transferred to the ER for loading onto MHC I class molecules. Although the precise mechanism of cross-presentation remains controversial, the ability of DCs to utilize this process to activate CD8⁺ T cells is well established. Peptides may escape from phagosomes through leaky membranes or by active transportation, allowing them access to cytosol. Gap junctions may also serve as a channel that allows peptide transfer from neighboring cells and subsequent availability for cross-presentation.

MHC Class I Antigen Presentation

MHC I molecules are expressed in almost all cell types and present cytosolic proteins, including cytosolic viral or bacterial proteins, to CD8⁺ T cells. They are composed of heavy chains and β 2 microglobulin, an invariant light chain.

Antigenic peptides are predominantly generated from the ubiquitin-proteasome system of ubiquitinated nascent proteins, misfolded proteins (retrotranslocated from endoplasmic reticulum [ER] to the cytosol through the ER-associated degradation pathway [ERAD]), neosynthesized defective proteins, defective ribosomal products (DRiPs), and proteins expressed in the cytoplasm. IFN- γ strongly influences processing efficiency by inducing immunoproteasome formation and proteasome activator PA28 synthesis.⁶⁴ DCs express immunoproteasomes containing the active site subunits LMP2, LMP7, and MECL-1, which enhance antigen processing and the generation of a different spectrum of peptides from the standard proteasome. Recently, intermediate immunoproteasomes were identified; they contain only one or two inducible catalytic subunits of immunoproteasome and confer different cleavage specificities. This broadens the repertoire of antigens presented to CD8⁺ T cells.⁶⁵

The peptides are transported to the ER through the transporter associated with antigen processing (TAP), where long peptides are further trimmed by ER aminopeptidase-1 (ERAP-1) to 8-mer or 9-mer peptides for loading onto MHC class I molecules. The trimeric complex of MHC class I heavy chains, β 2 microglobulin, and peptide allows for optimal folding, glycosylation, and delivery to the cell surface (see Figure 9-2).

Cross-Presentation

DCs can acquire antigens exogenously and process them for presentation by MHC class I molecules, referred to as *cross-presentation*.^{66,67} This property is atypical because MHC class I molecules exclusively present endogenous proteins in most cells. Cross-presentation requires peptides to gain access to cytosol, to be processed by proteasome, and to be transferred to the ER for loading onto MHC class I molecules (see Figure 9-2C). Although the precise mechanism of cross-presentation remains controversial, it is well established that DCs utilize this process to activate CD8⁺ T cells. DCs may acquire antigens in the form of apoptotic cells, necrotic cells, antibody-opsonized cells, immune complexes, heat shock proteins, and exosomes, and even by nibbling of live cells.^{52,66-69} Autophagosomes may be another source of peptides for MHC class I molecules. Autophagy clears ubiquitinated cytoplasmic protein aggregates.⁷⁰ Activation of DCs through TLR or exposure to stress induces DC aggresome-like structures (DALIS) containing polyubiquitinated proteins; peptides derived from DALIS can also be presented by MHC class I molecules.⁷¹

MHC Class II Antigen Presentation

The MHC class II pathway is constitutively expressed only by APCs. MHC class II $\alpha\beta$ heterodimers rely on a specialized type II transmembrane chaperone protein, the invariant chain (Ii), for stable assembly in the endoplasmic

reticulum.⁷² Ii stabilizes the MHC II complex and contains an endosomal sorting and retention signal.⁷² MHC class II molecules are transported and concentrated in multivesicular and multilamellar late endosomal compartments called the *MHC class II-containing compartment* (MIIC).

Antigens are endocytosed and retained within phagosomes before fusing with lysosomes to form phagolysosomes. Concomitant TLR signals induce activation of the vacuolar proton pump that enhances lysosomal acidification and antigen proteolysis within phagolysosomes.⁷³ Acidification of this compartment allows optimal activity of cathepsins. Cathepsin S degrades the cytoplasmic tail of Ii, leaving a short peptide, the MHC class II-associated invariant-chain peptide (CLIP), bound to the peptide-binding groove and thus protected from proteases. CLIP is replaced by an antigenic peptide in the endosome derived through the action of endosomal proteases on essentially any proteins accessing the endosome. The rate of dissociation of CLIP is too slow for quantitative peptide loading; the catalyst-chaperone protein HLA-DM accelerates the rate of CLIP release and peptide exchange in MIIC. The transport of loaded MHC class II molecules is thought to involve the transformation of MIIC into tubular structures directed toward the site of T cell interaction at the plasma membrane.⁷⁴

TLRs regulate phagosome maturation,⁷⁵ enhance lysosomal acidification,⁷³ and increase antigen uptake transiently.⁷⁶ MHC class II surface expression and turnover rates are regulated by cytoplasmic domain ubiquitination in DCs.⁷⁷ This explains the expression of low levels of MHC class II molecules by immature DCs and their increase in half-life after maturation, sustaining antigen presentation after migration into secondary lymphoid organs.

RA is characterized by autoantibodies against citrullinated proteins. A possible mechanism of generation of the immune response against citrullinated proteins has been recently described in mice.⁷⁸ It has been shown that two distinct conformers of MHC-peptide complexes are known for the same peptide; these are referred to as *type A* for stable conformation and *type B* for less stable conformation. Peptides generated from intact protein are loaded onto MHC class II complex in the late endosome/lysosome. In this compartment, HLA-DM catalyzes peptide loading and acts as a conformational catalyst, hence only more stable type A conformers are loaded.⁷⁸ In comparison, the same peptide may be loaded exogenously at the cell surface and in the early endosome in exchange for poorly binding peptides occupying MHC class II molecules in the absence of HLA-DM. These mechanisms of loading give rise to both stable type A and flexible type B conformers.⁷⁸ Hence only type A T cells are primed with native protein, and exogenous peptide gives rise to priming of both type A and B T cells. In the thymus, T cells recognizing the type A conformation for a peptide are deleted, whereas type B T cells escape thymic negative selection.⁷⁸ Thus self-reactive type B T cells are present in the naïve peripheral repertoire and have potential for autoimmune activation. This was recently shown in nonautoimmune prone mice after immunization with unmodified hen egg lysozyme (HEL); T cells specifically reactive to citrullinated epitopes of HEL were present among the responding repertoire to immunization.⁷⁹ The citrullinated HEL epitopes were processed and loaded onto MHC class II complexes and were presented to T cells by

DCs.⁷⁹ Hence naturally occurring self-reactive T cells, which have evaded thymic negative selection, may recognize citrullinated peptides loaded as flexible type B conformers onto MHC class II molecules and subsequently provide help for B cell-mediated antibody responses against citrullinated proteins.

Lipid Presentation

CD1 molecules present lipid antigen to T cells. The CD1 family of MHC I-like glycoproteins includes CD1a-d on the surfaces of DCs and CD1e, which remains in the endoplasmic reticulum. CD1a-c-restricted T cells express CD4 or CD8 or lack both CD4 and CD8 (double negative). By contrast, most CD1d-restricted T cells express a semi-invariant T cell receptor (TCR) and markers of NK cells and are identified as invariant NK T (iNKT) cells.⁸⁰

Similar to MHC I and MHC II molecules, CD1 molecules assemble in the ER, where they noncovalently bind the chaperones calnexin, calreticulin, ERp57, and $\beta 2$ microglobulin.⁸¹ Lipid antigens are generated by lysosomal hydrolases of internalized phagosomes, membrane-bound lipids in clathrin-coated vesicles, or internalized apoptotic bodies or exosomes and are loaded onto CD1 molecules.

T CELL ACTIVATION

cDCs interact with naïve T cells upon arrival in the lymph node and with effector memory T cells at inflammatory sites. DC-derived signals that determine the outcomes of these interactions include the following: antigen presentation in the context of MHC molecules (Signal 1), co-stimulatory molecules, including CD80 and CD86 (Signal 2), and cytokines (Signal 3). Expression of these signals by DCs is induced by exposure to PAMPs or DAMPs. Some cell surface molecules are inhibitory, such as PDL1 through negative interactions with T cell PD1, or CD80/CD86 with T cell CTLA-4. Signal 3—provided in *cis* by APCs to antigen-specific T cells—includes IL-12, IL-23, TNF, IL-6, IL-1 β , and type I IFN produced by DCs. Because cytokine secretion varies according to PRR activation, PAMPs and DAMPs are important factors, which skew the adaptive immune response.

T cell activation is dependent on the intensity and length of DC–T cell interactions, mediated by the immunologic synapse (IS), which is a region of spatially and temporally organized motifs of membrane proteins and cytosolic molecules formed at the interface between a T cell and a DC.⁸² Stable long-lasting contacts of APCs with T cells are dependent on co-stimulatory molecules and integrin molecules ICAM-1 and ICAM-3. These integrins form a ring in the outer part of the IS, in a region adjacent to the corresponding area containing lymphocyte function associated antigen-1 (LFA-1).⁸³ It is hypothesized that the stability of the IS confers temporal inhibition of DC apoptosis, which would enhance activation of clonal T cells in the lymph node.⁸²

CD4⁺ T helper (Th) cells play a vital role in the induction of humoral and cellular immunity, providing signals for the activation of B cells and CD8⁺ T cells. Controlled by the activated DCs, CD4⁺ T cells can differentiate into Th1 cells, producing IFN- γ and IL-2; Th2 cells, producing IL-4, IL-5, and IL-13; follicular helper T cells (Tfh), expressing

inducible T cell co-stimulator and producing IL-21; Th17 cells, producing IL-17; or regulatory T cells (Tregs), producing TGF- β or IL-10 (see Chapter 13).

DCs promote a Th1 phenotype by acting on both NK cells and naïve CD4⁺ T cells. Collaboration of IFN- γ and IL-12 induces and sustains Th1 differentiation. The Th2 response is promoted by induction of OX40 ligand (OX40L) on DCs, which is mediated by release of thymic stromal lymphopoietin (TSLP) by epithelial cells, mast cells, and basophils.⁸⁴ Absence or depletion of IL-12 production by DCs also skews the T cell response to Th2. In turn, IL-10 secretion by Th2 cells can negatively regulate DC function.⁸⁵ DCs make a deficient response to TSLP stimulation in Crohn's disease, an inflammatory bowel disease associated with Th1 and Th17 immunity.⁸⁶

Proinflammatory T cells expressing IL-17 were described in RA synovium as long ago as in 1998.^{87,88} Recently, Th17 cells expressing the ROR γ t transcription factor were described as a new subset of Th cells. Upon TLR stimulation, innate immune cells including DCs secrete IL-6 and IL-1 β . The presence of IL-6 and TGF- β induces Th17 differentiation, subsequent production of IL-21, and expression of IL-23R.⁸⁹ IL-1 β is also a critical amplifier of Th17 differentiation, especially in humans. IL-1 β and IL-6 also promote the reprogramming of FoxP3⁺ regulatory T cells to Th17.⁹⁰ This scenario is relevant to the development of autoimmune disease, as Tregs are selected based on intermediate affinity for self-peptides in the thymus.⁹¹ IL-21 amplifies Th17 differentiation; however, IL-23—produced by DCs—is needed for maintenance of Th17 cells.⁸⁹

Although Th1 cells were the major subset of T cells identified in RA synovium, identification of Th17 cells and the cytokines IL-17 and IL-23 within affected tissues and/or fluids has implicated both Th1 and Th17 cells in the pathogenesis of both RA and spondyloarthritis.^{88,92} Synovial tissue DCs express IL-12p70 and IL-23p19, providing a mechanism by which Th1 and Th17 cell production is locally perpetuated.⁹³

pDCs, potent producers of type I IFN, also present viral and tumor antigens to initiate both CD4⁺ and CD8⁺ T cell responses, thereby providing an important link between innate and adaptive immunity.^{94,95} Increased production of IFN- α may activate CD8⁺ T cells, which are increased in kidneys in lupus nephritis patients.^{96,97} In addition, pDCs can induce Treg generation by induction of indoleamine-2,3-dioxygenase (IDO) (discussed later).

B CELL ACTIVATION

B cells express both antigen-specific B cell receptors (BCRs) and various TLRs, thus allowing them to play a role in innate and adaptive immunity.

Although DCs present processed antigens to naïve T cells, B cells recognize antigen in its unprocessed native state. Two mechanisms of resistance to intracellular antigen degradation in DCs are described: (1) the internalization of antigen-containing immune complexes into nondegradative intracellular compartments through Fc γ RIIB, followed by receptor recycling to the cell surface and presentation to the BCR⁶¹; and (2) accumulation of intact antigen in neutral endosomes by DC-SIGN (carbohydrate-containing antigen).

When DCs and B cells take up the same antigen, DCs can activate B cells in an antigen-specific CD4⁺ T cell–dependent manner. This results in B cell activation and isotype switching to IgG, IgA, and IgE, as well as memory B cell generation in response to T-dependent antigens.

DCs can also stimulate B cell proliferation by expression of BAFF and its closely related tumor necrosis family member APRIL, a proliferation-inducing ligand.⁹⁸ Furthermore, inflammatory cytokines secreted by DCs can also affect B cell activation. IFN- α and IL-6, or ICAM-1, expressed by activated pDCs, regulate B cells to differentiate into plasma cells for T cell–independent antibody production.⁹⁹ IFN- α can enhance antibody secretion in vivo¹⁰⁰ and can induce cDCs to produce BAFF and APRIL; this triggers isotype switching independently of CD40 ligation.¹⁰¹

NK CELL ACTIVATION

DCs can induce activation and/or proliferation of NK cells, resulting in increased NK cell cytolytic activity and/or IFN- γ production. Both cell-cell contact–dependent interactions and soluble cytokine signals are involved. NKG2D ligands are cell contact–dependent signals expressed by DCs in response to stressful stimuli. LFA-1/ICAM-1 interactions have also been implicated in NK cell activation by DCs. Type I IFN augments NK cell cytotoxicity; IL-12 induces IFN- γ secretion and cell proliferation; IL-15 determines cell differentiation and survival; and others such as IL-18 and IL-2 are mediators in DC-mediated NK cell activation.

Reciprocally, NK cell–mediated activation of DCs depends mainly on cytokines, principally TNF and IFN- γ , whereas cell contact–dependent interactions are required for DC elimination. NK cells can lyse imDCs through NKp30—a process referred to as *DC editing*.¹⁰² A TRAIL-mediated mechanism and CD94-NKG2A–mediated signals also induce DC lysis.

DENDRITIC CELLS AND TOLERANCE

Self-tolerance is the ability of the immune system to deal with invading microorganisms (pathogenic antigens) while remaining inert to the body's constituents (self-antigens). A recent autoimmune model, in which cDCs, pDCs, and Langerhans cells were constitutively depleted from thymus and periphery, demonstrated the overall importance of DCs for self-tolerance.¹⁰³

Central Tolerance

Central (or thymic) tolerance defects are important and probably essential contributors to spontaneous autoimmune disease.¹⁰³ T cells are selected in the thymus according to their affinity for self-MHC molecules loaded with endogenous self-antigens displayed by thymic cortical epithelial cells. Those T cells reactive to self-antigen above a threshold of affinity for self-antigen–MHC complexes expressed and presented by medullary APCs are then deleted by negative selection. These APCs include medullary epithelial cells (mTECs) and medullary DCs expressing the marker SIRPa,¹⁰⁴ and they delete self-reactive T cells in the thymus in experimental settings.¹⁰⁵

In the medulla, mTECs express the transcription factor known as *autoimmune regulator* (AIRE), which controls the expression of peripheral tissue antigens (PTAs) such as insulin and salivary protein-1.^{106,107} In the absence of AIRE, glandular (salivary and lacrimal glands, liver, pancreas, thyroid) organ-specific autoimmunity develops.¹⁰⁸ In humans, this monogenic syndrome is known as *autoimmune polyglandular syndrome and candidiasis* (APECED).¹⁰⁹

In mice, thymic medullary DCs include CD11b⁺CD8⁺SIRPa⁺ DCs arising from proliferating intrathymic precursors, and extrathymically derived CD11b⁺CD8⁺SIRPa⁺ DCs.¹¹⁰ Both are located in the cortico-medullary junction, the site of negative selection. Medullary DCs can present self-antigens that they have captured from peripheral tissues before their traffic into the thymic medulla,^{104,111,112} or after uptake of apoptotic mTECs, which themselves express PTAs.¹¹³ mTECs progress to apoptosis after terminal differentiation and expression of AIRE, delivering PTA to DCs for the induction of central tolerance to self-peptides in the thymus.¹¹⁴

Although an affinity threshold applies for central deletion of self-reactive T cells, this threshold varies according to the susceptibility of thymocytes to death and the capacity of the T cell receptor and its signaling pathways to transmit an activation signal. Efficiency of self-antigen presentation also depends on the ability of thymic APCs to process and present self-antigen, and the density of MHC and co-stimulatory molecules expressed by the APCs.¹⁰⁵ Although selection of CD4⁺CD25⁺ SP thymocytes occurs in the cortex, FoxP3⁺ thymocytes are located in the medullary regions, and DCs from the periphery can migrate to the medullary and play an important part in their development.¹⁰⁴

Peripheral Tolerance

Peripheral tolerance mechanisms provide a second level of control to restrain potentially autoreactive T cells, which migrate into the periphery from the thymus. This is necessary because of the stochastic nature of deletional central tolerance, which is based on affinity thresholds. Deletion is also used as a peripheral tolerance mechanism, where resting DCs derived from hematopoietic progenitor cells have been shown to delete autoreactive CD8⁺ T lymphocytes.^{115,116} This deletion of T cells autoreactive toward specific auto-antigenic determinants is also known as *recessive tolerance*. In addition, “dominant” peripheral tolerance mechanisms involve suppression or regulation of the proliferation and effector functions of autoreactive T cells by Tregs.¹¹⁷ Although antigen-specific, regulatory mechanisms are able to suppress toward a wider range of determinants as the result of bystander or *infectious tolerance* mechanisms.¹¹⁸

“Natural (n)” CD25⁺FoxP3⁺ Tregs are produced centrally, selected by recognition of self-antigen at intermediate affinity by cTECs, and potentially also by mTECs and thymic DCs.¹¹⁹ However, DCs also induce or promote the generation of peripheral Tregs, known as *induced (i)Tregs*. This occurs in several contexts. CD103⁺ DCs located in gut epithelium and draining mesenteric lymph nodes stimulate the peripheral conversion of FoxP3⁺ Tregs from naïve T cell precursors. These specialized lamina propria DCs express retinal dehydrogenase, which catalyzes the conversion of

retinal to retinoic acid.^{16,120,121} In vitro, this conversion is recapitulated by stimulation of naïve T cells with DCs in the presence of mitogenic anti-CD3 and TGF- β .¹²² Another FoxP3⁺CD25⁻ iTreg population known as regulatory type 1 (Tr1) cells expresses high levels of IL-10 and IFN- γ and typically is induced by DCs generated in the presence of, and expressing high levels of, IL-10.¹²³ In humans this small DC subset is marked by expression of CD16, CD14, immunoglobulin-like transcript (ILT)4, and HLA-G.¹²³ Finally, FoxP3⁺ Tregs may be induced in the periphery and may develop greater suppressive function as a result of T cell exposure to the enzyme indoleamine-2,3-dioxygenase (IDO). IDO is expressed upon activation of various APCs, including pDCs and cDCs, and depletes tryptophan from the environment by metabolizing it to kynurenine, thus starving T cells of an essential amino acid required for cell growth and viability.^{22,124} Although IDO probably plays little role in the maintenance of tolerance in the resting state, it is strongly induced by NF κ B signaling in response to certain inflammatory signals, including TLR7 and TLR9 activation by single-stranded RNA and CpG, respectively, immunostimulatory sequences, type I and type II IFN, and “back-signaling” by the T cell activation-induced cell surface molecules CTLA4 and glucocorticoid-induced TNFR-related protein (GITR), which ligate CD80/CD86 and GITR-ligand respectively, expressed by DCs.^{125,126} GITR-ligand is also induced by glucocorticoids. Thus, IDO⁺ DCs induced by inflammatory signals and activated T cells promote the generation of FoxP3⁺ Tregs with timing that ensures regulated expansion of activated T cells and other innate inflammatory pathways. pDCs appear to induce IDO activity and FoxP3⁺ Tregs particularly effectively; this role may be even more important than that of immunogenic antigen presentation for this subset.^{22,127} They may use additional mechanisms, such as granzyme B, to regulate effector T cell function.¹²⁸

In chronic inflammatory settings, such as RA and juvenile rheumatoid arthritis (JRA), IDO⁺ APCs and FoxP3⁺ T cells are thus enriched, relative to healthy tissues.¹²⁹⁻¹³² However, mechanisms such as inhibition of regulatory function by proinflammatory actions of TNF and IL-6 or expression of tryptophanyl-t-RNA-synthetase inhibit regulatory function or the response of effector cells to regulation.^{90,129,133}

The discovery that DCs generated ex vivo could be exposed to antigen and transferred to naïve recipients to prime immunity spawned many experiments in mice with subsequent translation to human clinical trials in which DCs were employed as a natural adjuvant for vaccination.^{134,135} The subsequent discovery that Tregs could be induced by adoptive transfer of antigen-exposed modified DCs opened possibilities of restoration of tolerance and suppression in mouse models of autoimmune disease and allografting, with recent translation to clinical trials in RA and type 1 diabetes.¹³⁶ DCs with the capacity to regulate inflammation through iTregs typically present antigen with intermediate affinity to T cells (e.g., suboptimally activated DCs, which present small amounts of antigen, DCs lacking co-stimulatory molecules or expressing suppressive molecules such as IL-10, IL-4, or Fas-ligand).^{137,138} Antigen-exposed DC deficiency in the NF κ B subunit RelB induced antigen-specific Tregs and suppressed disease after adoptive

transfer into wild-type hosts with inflammatory arthritis.^{139,140} Similar effects occurred upon transfer of antigen-loaded DCs that had been transfected with RelB siRNA.¹⁴¹ These experiments identified NF κ B RelB as a critical regulator of DC antigen-presenting function.¹⁴² The PI3K/mammalian target of rapamycin (mTOR) is a second major regulatory pathway regulating the interactions between DCs and regulatory and effector T cells.¹¹⁸ Thus DCs generated in the presence of rapamycin, an inhibitor of mTOR, induced antigen-specific Tregs and suppressed rejection after adoptive transfer into allograft recipients.¹⁴³ Wnt/ β -catenin is a third major regulatory pathway involved in DC function. β -Catenin was recently shown to be constitutively active in intestinal DCs and to regulate the balance between FoxP3⁺ Tregs and Th17 effector cells in the lamina propria through induction of retinal dehydrogenase.¹⁴⁴ In vitro, disruption of E-cadherin signaling in DC cultures activated this pathway and their capacity to induce Tregs.¹⁴⁵ Enhanced and prolonged ERK signaling has also been shown to be important for suppression of IL-12 and induction of IL-10 secretion by DCs, which promote tolerance.¹⁴⁶ This includes TLR2-dependent (e.g., by bacterial teichoic acids) and TLR2-independent signals (e.g., by C5a and cigarette smoke-induced oxidative stress).¹⁴⁷

Many other approaches have been developed using immunomodulatory drugs for generation of DCs with similar capacity to induce Tregs and suppress disease after adoptive transfer. These include combinations of immunomodulators, which turn out to block NF κ B and to activate IDO and ERK, such as vitamin D, glucocorticoids, and lipoteichoic acid,¹⁴⁸ or molecules with the capacity to induce partial activation by DCs, thus preventing further induction of immunogenic molecules, such as IL-12, resulting in a “semi-mature” or “tolerant” state. The semi-mature state can be induced by chronic exposure to TNF, IL-6, or low-dose endotoxin.^{149,150} It has also been proposed that exposure to chronically increased levels of IL-6—as occurs in RA or chronic infection, or in the context of various tumors—can promote a tolerant DC phenotype in vivo.¹⁵¹

Appreciation of the critical pathways regulating DC function has led to a number of successful approaches in mouse models to target DC to promote tolerance. Inflammatory arthritis was suppressed in mice delivered arthritogenic antigen packaged into liposome nanoparticles with an NF κ B inhibitor targeting phagocytic APCs in situ.¹⁵² CD40-antisense oligonucleotides packed into liposomes similarly downregulated CD40 expression after targeting phagocytic APCs and blocked collagen-induced arthritis (CIA).¹⁵³ Delivery of CTLA4-Ig (abatacept) to mice with CIA modified DCs and induced FoxP3⁺ Tregs.¹⁵⁴ More specific targeting of CD205⁺ DCs with proteolipid protein autoantigen conjugated to anti-DEC-205 suppressed experimental allergic encephalomyelitis in mice through induction of Tregs.¹⁵⁵ More indirectly, regulatory DCs expressing high levels of IL-10 and TGF- β were induced by administration of probiotics.¹⁵⁶

AUTOIMMUNITY

In autoimmune diseases, when tolerance against self-determinants is impaired, activated autoreactive T and B

cells and inflammatory innate immune and parenchymal cells participate in the process of tissue damage. DCs play an essential role in T cell priming in autoimmune disease, following translocation of antigens (including those modified [e.g., citrullinated] by the inflammatory process) from the periphery to secondary lymphoid organs and their presentation to naïve T cells,^{157,158} but also locally at the inflammatory site. Here they act as both local APCs and effector cells, producing proinflammatory molecules and regulating other effector cells. In different autoimmune conditions, cDCs and pDCs are enriched in inflamed tissues, particularly in a perivascular distribution. Moreover, DCs infiltrate tissues at very early stages of disease, where they contribute to the recruitment and organization of other immune cells. For example, in mice, DC infiltration is an early feature of islet cell autoimmunity in diabetes mellitus¹⁵⁹ and contributes to local lymphoid tissue formation in the pancreas.¹⁶⁰ Organization of tissue into lymph node-like structures, including lymphoid follicles, is a common feature of tissues affected by autoimmune inflammation,¹⁶¹ which contain follicular DCs (FDCs) and nurse-like fibroblast-like synoviocytes, supporting chronic production of autoantibodies.¹⁶²⁻¹⁶⁴

Here we discuss prototypic autoimmune rheumatic diseases and the role that DCs play in their initiation and progression.

Systemic Lupus Erythematosus

In SLE, an increased load of apoptotic material has been related to induction of the disease and its severity.^{56,165} Complement receptor 3 (CR3), a heterodimer of CD11b and CD18, is an apoptotic receptor that takes up apoptotic cells coated with C3bi. Recently, a variant of ITGAM (CD11b) has been discovered as a risk factor for SLE.⁵⁴ The IFN- α pathway is strongly linked to SLE pathogenesis, both biologically and genetically. Several genes for factors upstream and downstream of IFN and TNF production, such as *IRF5*, *STAT4*, *TNFAIP3*, and *TYK2*, have been associated with SLE susceptibility.¹⁶⁶ Additionally, *TREX1*, a gene encoding protein involved in degradation of nicked DNA, has been associated with SLE susceptibility.¹⁶⁶ It is proposed that reduced apoptotic clearance and thus availability of autoantigens in an immunogenic format for antigen presentation and uncontrolled IFN production by DCs can mediate SLE pathogenesis and maintenance.

Under normal conditions, uptake of apoptotic material in the absence of inflammatory cytokines promotes DC tolerance through stimulation of TGF- β and induction of Tregs. Dysregulated clearance of apoptotic cells leads to an accumulation of blebs with modified autoantigens. Apoptotic blebs containing endogenous danger signals or alarmins such as HMGB1 or antimicrobial peptides complexed with nucleosomes can activate DCs.^{31,167} Also, in already primed individuals, DNA-containing chromatin bound to autoantibodies can activate pDCs through TLR9. However, cDC activation by TLR9-independent activation and TLR7-dependent mechanisms has also been described because cDCs do not express TLR9.¹⁶⁸⁻¹⁷⁰ Moreover, uptake of autoantigens into lysosomal-associated membrane protein 1 (LAMP1)⁺ endocytic compartments of cDCs may be critical for effective antigen presentation.³⁰ Furthermore, an

increase in the number of circulating Th17 cells and a decrease in the number of Treg cells have also been recorded; these were associated with disease flares of SLE.¹⁷¹ In addition, hyperactivation of IL-17 and IL-23 has been observed in SLE patients.¹⁷²

Although T cells initially primed by DCs may be specific for modified autoantigens, epitope spreading accounts for activation of B cell responses against modified and unmodified autoantigens. A model, which proposes a pivotal role for DCs in the initiation and progression of SLE, indicates that antibodies opsonize autoantigens and activate pDCs, which will amplify autoimmune responses primed by cDCs.¹⁶⁵

Rheumatoid Arthritis

DCs are thought to contribute to ongoing inflammation through presentation of autoantigens, as suggested by animal models of RA in which DCs have been depleted, or through proinflammatory (including capacity for cartilage destruction) and regulatory effector functions.¹⁷³⁻¹⁷⁶ For instance, joint DCs and monocyte-derived DCs can present human cartilage glycoprotein 39 (HCgp39) and epitopes from synovial fluid (SF) to antigen-specific T cells, respectively.¹⁷⁷ Further evidence for the contributing role of DCs to disease initiation and perpetuation in RA and the spondyloarthropathies derives from the substantial accumulation of immature and mature DC subsets, including cDCs and pDCs perivascularly in inflamed synovium, in close association with T and B cell follicles.¹⁷⁸⁻¹⁸³ This accumulation of DCs contains the most significant numbers of mDCs and pDCs identified in any human inflammatory site.^{93,178,184} DCs expressing markers of both differentiated and undifferentiated cells have been identified in RA synovial tissue. Evidence of prior activation in vivo includes upregulation of MHC, co-stimulatory molecules such as CD86,¹⁷⁹ and RelB¹⁸⁰; expression of receptor activator of nuclear factor κ B (RANK) and its ligand (RANKL)¹⁸⁵; and heightened production of proinflammatory cytokines ex vivo (e.g., IL-1, IL-6, TNF) in response to stimulation with immune complexes or TLR agonists.¹⁸⁶ Migratory DCs may undergo maturation in response to locally produced cytokines, or to endogenous factors released during inflammation (e.g., HMGB1, HSPs).¹⁸⁷ These DCs may have migrated into the joints in response to locally produced cytokines and chemokines (CCL19 to CCL21) or may differentiate locally from myeloid progenitors in response to growth factors contained within SF.¹⁸⁸ Expression of nuclear RelB and CCR7 is associated with cells expressing CCL19 and CCL21.^{179,189,190} Ectopic expression of CCL19 is sufficient for formation of lymphoid tissue similar to that seen in rheumatoid synovial tissue.¹⁹¹ In contrast, immature DCs in the synovial lining and in sublining layers are characterized by CCR6 expression and are associated with CCL20-expressing cells.¹⁹⁰

The number of CD304⁺ pDCs expressing type I IFN and IL-18 was found to exceed that of the CD1a⁺ subset of cDCs, expressing IL-12 and IL-23 in RA synovium, particularly in patients positive for RF and anticitrullinated protein antibodies (ACPAs).⁹³ RA synovial pDCs also displayed immunoreactivity for IDO.¹⁹² In RA and JRA peripheral blood, cDCs were found to be reduced relative to healthy

peripheral blood, and this reduction correlated with disease severity,^{193,194} supporting the idea that migration to synovium is increased by inflammatory chemotactic activity. On the other hand, the number of peripheral blood pDCs in RA correlated inversely with the development of antinuclear antibodies and increased serum IFN- α following TNF inhibition with infliximab.¹⁹³ In the peripheral blood of children with systemic JRA, cDCs were decreased and peripheral blood (PB) monocytes were increased during flares.¹⁹⁵

Increased numbers of cDCs and pDCs have been shown in SF. cDCs are threefold to fourfold enriched in fresh synovial fluid compared with the blood or with osteoarthritis SF and are more differentiated than blood DC precursors.^{193,196,197} SF DCs and blood DCs stimulate resting allogeneic T cells with equivalent efficacy, and more efficiently than SF monocytes. However, SF DCs are markedly more efficient stimulators of autologous T cells in the absence of exogenous antigen, suggesting that their MHC molecules are loaded with relevant RA autoantigens.¹⁹⁶

RA was initially believed to be exclusively Th1 driven. However, identification of Th17 cells and its cytokine IL-17 within affected tissues and/or fluids now implicates both Th1 and Th17 cells in its pathogenesis.⁸⁸ DCs are required for the differentiation of both subsets from naïve precursors. Th1 cells, which produce IFN- γ , activate macrophages to produce proinflammatory cytokines (IL-1, IL-6, and TNF), induce immunoglobulin class switching to complement-fixing antibodies. IL-17 recruits leukocytes and stimulates IL-1 and TNF production by human macrophages, which altogether stimulate activation of synovial fibroblasts.¹⁹⁸ Th17 cells mediate bone destruction in RA by stimulating osteoclastogenesis through RANK-RANKL interactions.¹⁹⁸ Subsets of synovial DCs express IL-12 or IL-23—cytokines essential for full differentiation of Th1 and Th17 cells, respectively—providing a mechanism by which their production is locally facilitated or perpetuated.

In RA synovium, ectopic lymphoid organs resembling germinal centers (GCs) support autoantibody production because they express activation-induced cytidine deaminase (AID) and are surrounded by ACPA-producing plasma cells.¹⁹⁹ In RA, ACPA and rheumatoid factor antibodies are presumed to bind to Fc receptors on macrophages and DCs, thereby inducing their activation and production of proinflammatory cytokines.²⁰⁰ Indeed, synovial DCs from active RA patients have markedly upregulated Fc γ RII.¹⁸⁶ pDCs have also been found in rheumatoid synovium and through production of IFN- α may enhance autoantibody production.²⁰¹ Indeed a substantial number of RA patients express an IFN- α signature associated with ACPA production.²⁰²

Altogether, human data strongly suggest multiple roles for DCs in rheumatoid synovium, in local inflammation, joint destruction, and immune regulation. These data complement murine studies of inflammatory arthritis, which establish the important role of DCs in priming, inflammatory responses, and regulation of arthritic autoimmune responses.

Sjögren's Syndrome

Sjögren's syndrome (SS) is characterized by infiltration of mononuclear cells into exocrine, predominantly salivary

and lacrimal, glands. Infiltrating cells are mainly CD4⁺ T cells but also may be CD8⁺ T cells, B cells, and some plasma cells.²⁰³⁻²⁰⁵ Sjögren's syndrome-related autoantibodies include SSA/Ro, SSB/La, antinuclear antibodies, and rheumatoid factor.

Germinal center formation with FDC networks has been shown in the salivary glands of SS patients,²⁰⁶⁻²⁰⁸ possibly attracting lymphocytes to the site. FDCs have also been implicated to function as accessory cells for B cell function.²⁰⁹ Mouse models of SS showed that DC infiltration precedes lymphocyte infiltration into the submandibular gland,²¹⁰ suggesting the initiating role of DCs in disease development. Increased numbers of mature DCs were detected in a mouse model and in human SS patients.^{211,212} pDCs were detected in the salivary glands of SS patients but not of healthy controls,²¹³ whereas decreased levels of pDCs in the blood of SS patients indicate their recruitment into salivary glands.²¹⁴ Given the role of pDCs and the increased levels of antinuclear antibodies and of type I interferon in the salivary glands,^{213,215} several studies have investigated the role of Epstein-Barr, hepatitis C, human T-lymphotropic virus type I (HTLV-1), and coxsackievirus in patients with SS,²¹⁶⁻²¹⁹ but no evidence has been found to support their direct involvement.

Seronegative Spondyloarthropathies (SpA) and Psoriasis

Bacteria are thought to be involved in the pathogenesis of psoriasis and psoriatic arthritis.^{220,221} Because the innate immune system is the first line of defense against bacteria, innate responses have been studied in these patients. PB DCs in psoriatic arthritis (PsA) patients and keratinocytes and dermal DCs of psoriatic skin lesions express high levels of TLR2.²²²⁻²²⁴

pDC numbers are increased and the type I IFN signaling pathway is activated in psoriatic skin.²²⁵⁻²²⁸ Furthermore, blocking of pDC or IFN signaling in skin xenograft models prevented the development of psoriasis.²²⁹

Keratinocytes play important roles in secreting antimicrobial peptides and DC chemoattractants. Antimicrobial peptide LL37 has been shown to bind self-DNA and to trigger type 1 IFN in psoriasis.³¹ Dermal DCs are increased in psoriatic skin and induce proliferation of autoreactive T cells, inducing a Th1 response.²³⁰ A subset of dermal DC, known as Tip-DC, produces inducible nitric oxide synthase (iNOS) and TNF, promoting a proinflammatory environment.²³¹

In psoriatic lesions, a vicious cycle develops, in which activated T cells produce TNF and IFN- γ , which activate keratinocytes to produce a wide variety of cytokines,^{229,232} resulting in DC activation.²³³ Chemokines attract lymphocytes into the site. However, the trigger is unknown.

The importance of HLA-B27 in spondyloarthropathies is well defined, but recent genetic studies demonstrate the involvement of innate immune system defects in the development of not only ankylosing spondylitis (AS) but also psoriasis and Crohn's disease. These include *IL23R*, *IL12B*, *STAT3*, and *Card9*.²³⁴⁻²³⁶ These findings support research indicating the importance of IL-17 in disease pathogenesis in SpA, and suggesting possible involvement

of fungal recognition in DCs,²³⁷ inducing a Th17 response in T cells.

In HLA-B27 transgenic rats, a defective stimulatory capacity of DCs has been detected.^{238,239} HLA-B27 in this model also induces the unfolded protein response,²⁴⁰ leading to reduction of MHC class I²⁴¹ and IL-23 production,²⁴² which seems to play an important role in SpA.

Similar to other seronegative arthritides, pDCs are increased in synovial fluid but not in PBs in SpA patients.¹⁸³ These pDCs were more immature than cDCs when costimulatory markers, including CD40, CD83, and DC-LAMP, were analyzed. Thus defective DC APC function may be an important factor in the initiation or perpetuation of SpA.

Future Directions

DCs are a heterogeneous population of bone marrow-derived mononuclear cells that are found in an immature state in virtually all tissues in the body. DCs are professional antigen-presenting cells with a capacity to stimulate naïve T cells, as well as B cells and NK cells, and initiate immune responses. They are involved in the progression and maintenance of autoimmune diseases and can modify both innate and adaptive immune responses to derive autoimmune pathology. This central role of DCs makes them an ideal candidate for therapeutic targets. They can be modulated in an antigen-independent manner or can be targeted by antigen-dependent means.

Anti-TNF, IL-6, and CTLA4-Ig therapies are successfully being used for RA and serve as examples of antigen-independent therapies that directly target APCs. However, the mechanism underlying immunomodulation of these therapies is still being determined. Recently, tolerogenic DCs (TDCs) were being used in an antigen-dependent manner to treat RA. However, to maximize antigen-dependent DC immunomodulatory activity in vivo, relevant antigens for autoimmune diseases need to be identified to ascertain the most efficient way to generate TDCs. Given the expansion of knowledge of genetic defects linked to autoimmunity, it should become possible to tailor DC therapy in the future to gain maximum benefit.

Mononuclear Phagocytes in Rheumatic Diseases

SIAMON GORDON

KEY POINTS

Macrophages play an important role in tissue homeostasis and in cellular and humoral innate and adaptive immunity.

Macrophages, dendritic cells, and osteoclasts are derived from blood monocytes.

Tissue macrophages display marked phenotypic heterogeneity, depending on their local microenvironment.

Distinct subsets of monocytes are recruited to inflammatory sites in tissues.

Microbes and cytokines (e.g., interferon- γ , interleukin [IL]-4, IL-10) selectively regulate macrophage activation.

Macrophages express a range of opsonic and nonopsonic receptors to recognize and take up foreign and altered host components.

Toll-like membrane and nucleotide oligomerization domain (NOD)-like cytosolic receptors induce alterations in macrophage gene expression and secretion of inflammatory mediators.

Macrophages and their products contribute to tissue damage and repair and to chronic inflammation and autoimmunity.

Mononuclear phagocytes are widely distributed, biosynthetically active cells derived from hematopoietic precursors that circulate as monocytes and enter tissues constitutively and in response to inflammatory stimuli. In connective tissue and bone, they play a major role in homeostasis, growth, and remodeling as mature macrophages and osteoclasts (Figure 10-1). Myeloid dendritic cells (DCs) represent a distinct form of differentiation, specialized to maintain immune tolerance or to induce humoral and cellular immunity through B lymphocytes and T lymphocytes. Through their recognition, antigen-presenting, regulatory, and effector mechanisms, mononuclear phagocytes contribute to a range of inflammatory, infectious, autoimmune, metabolic, and degenerative rheumatic diseases, providing targets for therapeutic intervention.

Growth of knowledge in mononuclear phagocyte biology has developed in close association with understanding of pathogenesis and treatment of chronic arthritis. Relevant examples include the development of steroidal and nonsteroidal anti-inflammatory agents and of anti-tumor necrosis factor (TNF) monoclonal antibodies.¹ Genetic lesions in macrophage colony-stimulating factor (M-CSF) cause osteoclast deficiency and osteopetrosis in mouse models, whereas human mutations in cytosolic nucleotide oligomerization domain (NOD)-like receptors (NLRs) result in interleukin (IL)-1 β overproduction and hyperinflammatory

syndromes,² often associated with persistent joint disease. Immune complex deposition and complement activation combine with Toll-like receptor (TLR) recognition to induce effector pathways of tissue destruction and repair.

This chapter reviews general aspects of mononuclear phagocyte differentiation, recruitment, and activation, integrating the properties of different cellular subtypes. Studies on the biology of macrophages, DCs, and osteoclasts have diverged to the extent that common features have been overlooked in the understandable search for specificity. This review is an attempt, in part, to reintegrate these differentiated sublineages. General features especially relevant to physiologic and pathologic consequences of their presence in bone, joints, and connective tissues are discussed, and gaps in our knowledge are pointed out. The emphasis is on studies in humans, where available, with reference to murine models where applicable. The subject area encompasses innate and acquired immunity, autoimmunity, and *osteimmunology*,³ a reflection of local specialization of mononuclear phagocyte and lymphocyte biology. Relevant topics discussed elsewhere in this textbook include innate immunity (see Chapter 18), cytokines and chemokines (see Chapter 26), osteoclast functions (see Chapter 4), and anti-TNF therapy (see Chapter 63). For further details in connection with macrophage⁴⁻⁷ and DC biology,⁸⁻¹⁰ see reviews cited in this chapter.

OVERVIEW

Circulating monocytes give rise to tissue macrophages, which display considerable phenotypic microheterogeneity in different organs.⁷ Similarly, and with some overlap in properties, myeloid DCs are present as heterogeneous sentinel cells at mucosal and cutaneous surfaces,⁹⁻¹¹ undergoing a complex maturation process as they migrate to lymphoid organs after capture of antigens. Plasmacytoid DCs may represent a distinct sublineage, specialized to produce high levels of type I interferon in response to viral stimuli. Mononuclear precursors in the blood give rise to multinucleated osteoclasts, specialized to resorb bone.¹² Circulating monocytes are themselves heterogeneous, using distinct chemokine and adhesion receptors to give rise to different tissue mononuclear phagocytes.¹³ These cells differ in life span depending on the recruitment stimuli and on local factors in their environment, and they express diverse plasma membrane receptors, making it possible for them to interact with many different cell types and with microbial and modified host components. Phagocytosis is a hallmark of the ability of macrophages and DCs to engulf particulates, including foreign materials, bacteria,¹⁴ and dying host cells generated by apoptosis or necrosis.¹⁵

Figure 10-1 Thin section of a bone marrow-derived mouse macrophage. Cells were cultured for 7 days and were fixed and processed for conventional electron microscopy. Ly, lysosome; M, mitochondrion; N, nucleus. (Courtesy Chantal de Chastellier, Centre d'Immunologie de Marseille-Luminy, Marseille, France.)

These particulates are recognized by nonopsonic receptors, including scavenger and lectin-like receptors, or after opsonization with antibodies or complement or both that enhance uptake via Fc and complement receptors. In addition, other humoral proteins, such as Pentraxins, interact with their target ligands,¹⁶ bridging them to less well-defined macrophage receptors, which regulate early cellular responses during innate immunity. TLRs play an important role in sensing the nature of the captured cargo, often interacting with the extensive repertoire of non-TLR receptors (NTRs). An extended family of NOD-like receptors (NLRs) senses various cytosolic ligands, resulting in a complex assembly of proteins (inflammasomes), caspase activation, and release of IL-1 β .¹⁷ Uptake of particulate and soluble antigen, directly or by “cross-priming,”¹⁸ induces DC maturation, processing, and association with major histocompatibility complex (MHC) II molecules, as well as presentation of peptides to naive CD4 T lymphocytes. Endogenously generated or foreign peptides generated during biosynthesis of virus glycoproteins associate with MHC I molecules for surface recognition by cytotoxic T cells (mainly CD8). DCs and possibly macrophages regulate T cell activation or tolerance through additional co-stimulatory surface antigens and cytokines, depending in part on concomitant TLR stimulation. Activated T lymphocytes and their products, such as interferon- γ , IL-4/IL-13, and IL-10, regulate the effector functions of mononuclear phagocytes.

Digestion of macromolecules occurs in the vacuolar compartment involving dynamic membrane traffic and interactions with the cytoskeleton. Complex intracellular pathways transduce surface and vacuolar-derived stimuli to initiate formation of intracellular protein signaling complexes.

Transcription factors translocate to the nucleus and form activation or inhibitory chromatin-binding complexes that regulate gene expression and biosynthesis of secretory products, such as TNF. Other low-molecular-weight metabolites are generated by nontranscriptional mechanisms, yielding inflammatory mediators and antimicrobial activities. Osteoclasts are able to secrete hydrochloric acid (HCl) and potent proteolytic enzymes into sealed-off localized areas of bone, to which they adhere tightly through specialized podosomes and actin rings.

The secretory activities of mononuclear phagocytes influence a range of cellular and extracellular targets to maintain tissue homeostasis but also are responsible for tissue destruction. Their trophic actions,¹⁹ through cellular contact with other stromal cells and extracellular matrix and secretion, regulate tissue catabolism, cell growth, angiogenesis, and repair. In addition to local effects, macrophages contribute to systemic integration of proinflammatory and anti-inflammatory effects, acting on the central nervous system, endocrine organs, liver, and energy stores.

Overall, the activation phenotype of mononuclear phagocytes is modulated by extrinsic factors (e.g., cytokines, hormones), by balance of surface receptors with activating/inhibitory cytoplasmic motifs, by cytosolic regulators such as suppressors of cytokine synthesis (SOCS)²⁰ proteins, by phosphorylation/dephosphorylation of signaling molecules, and by assembly of transcription factor complexes on chromatin. Microarray analysis of macrophages has made it possible to distinguish characteristic signatures of gene expression after innate activation via TLRs, deactivation via glucocorticoids, or modulation via cytokines. As a result, the phenotype of tissue macrophages is markedly heterogeneous, making for complexity of function in different sites in health and disease, but also providing opportunities for novel state-specific or tissue-specific targeting by drugs.

LIFE HISTORY AND HETEROGENEITY (MACROPHAGES, DENDRITIC CELLS, AND OSTEOCLASTS)

In an adult, all three sublineages of mononuclear phagocytes originate from CD34⁺ committed progenitor cells in the bone marrow (Figure 10-2). These diverge from lymphoid cells and subsequently from polymorphonuclear leukocytes, although many genes are still expressed but not translated in both types of phagocytic cell. In vitro, bone marrow and blood monocytes can be stimulated by growth factors²¹ to generate macrophages (M-CSF or granulocyte-macrophage colony-stimulating factor [GM-CSF]), DCs (GM-CSF, with or without IL-4), or osteoclasts (M-CSF and RANK ligand). Some of these growth factors also are essential in vivo (e.g., osteopetrotic, M-CSF-deficient mice lack many but not all populations of tissue macrophages and osteoclasts).^{22,23} Monocytopoiesis is less well understood in humans and may depend on M-CSF and GM-CSF. Trophic interactions between hematopoietic precursors and stromal cells in the bone marrow (mesenchymal and hematopoietic in origin) are mediated by cell contact, via surface receptors,¹⁹ and by soluble factors (e.g., c-kit ligand and IL-1). Transcription factors that are essential for monocyte/macrophage production and related cells include Pu-1,

Figure 10-2 Differentiation and distribution of mononuclear phagocytes. Distinct subpopulations of circulating monocytes are thought to give rise to resident tissue macrophages (MØ), dendritic cells (DCs), and osteoclasts compared with cells recruited by an inflammatory stimulus. Further phenotypic heterogeneity arises from microenvironmental stimuli, such as cytokines and microbial products. For additional details of morphologic and other properties of cells in different tissues, see Gordon⁶ and Gordon and Hughes.⁷

other Ets family members, Maf,²⁴ and Mi, implicated in microphthalmia.

Although bone marrow precursors proliferate vigorously as they differentiate in the presence of M-CSF or GM-CSF, monocytes become refractory to these growth stimuli. Local macrophage proliferation can be induced by IL-4 during Th2 inflammation.^{24a} Restriction of DNA synthesis is associated with chromatin condensation, whereas RNA and protein synthesis persists and can be modulated by a variety of stimuli, as is discussed further subsequently.

Tissue macrophages, DCs, and osteoclasts all derive from circulating monocytes, although these already may display heterogeneity (see Figure 10-2). Recent studies in transgenic mouse models and in humans have described progenitor cells and precursor-product relationships in monocyte-macrophages, as well as DC differentiation.¹¹ Cells are recruited constitutively to peripheral sites in the steady state. A subset of patrolling monocytes may not leave the vasculature in the steady state. Additional monocytes can be recruited to local sites in response to infectious, inflammatory, and metabolic stimuli. Such “elicited” cells display distinct properties from the “resident” cells, which, in the case of macrophages and DCs, also display marked diversity, depending on their location. A considerable body of evidence indicates that different subsets of macrophages and DCs originate from distinct monocyte populations in peripheral blood.²⁵⁻²⁸ Apart from marker antigens (e.g., CD14, the receptor for lipopolysaccharide-binding proteins; Gr-1, a mouse Ly-6 antigen expressed by polymorphonuclear neutrophils and by some monocytes), levels of

chemokine receptors for fractalkine (CX3CR1) and CCR2 (MCP1) seem to distinguish monocyte subsets that give rise to inflammatory and resident macrophages (see Figure 10-2). Resident macrophages and immature DCs are present in many lymphohematopoietic and nonlymphoid organs; selected markers and properties are listed in Table 10-1. The CD68 antigen, a late endosomal mucin-like glycoprotein related to the lysosome-associated membrane protein (LAMP) family, is the most broadly expressed marker for all mononuclear phagocytes, although its function is still obscure.

Osteoclasts and resident macrophages are found on the surface of bone and display distinct phenotypes. Although antigenic markers for human and mouse mononuclear phagocytes are useful for phenotypic analysis, no single marker is definitive in their classification, and it is impossible, in most tissues, to distinguish locally activated resident cells from “elicited,” newly recruited, and locally activated monocytes. This problem is due in part to rapid modulation of antigen expression in blood monocytes when they enter a particular tissue microenvironment. Species differences in anatomy and in marker expression are a further confounding factor.

Apart from the expression of chemokine receptors,²⁹ adhesion molecules play a role in selective monocyte “homing,” but their differential expression by macrophages, DCs, and osteoclasts is less well defined than for lymphocyte subpopulations. These include various heterodimeric integrins implicated in adhesion to endothelium, to extracellular matrix, and to bone. There is considerable scope for

Table 10-1 Selected Properties of Mononuclear Phagocytes and Related Cells

Monocytes/Macrophages: Antigen Marker
F4/80 (mouse)
EMR2-EGF module containing receptor (human)
CD68
Complement receptor 3 (CR3) (CD11b)
Sialoadhesin (SIGLEC-1)
Scavenger receptors:
Scavenger receptor A (SR-A)
Macrophage receptor collagenous domain (MARCO)
Mannose receptor
Macrophage colony-stimulating factor receptor (M-CSFR)
Other properties:
Opsonic phagocytosis
Lysozyme secretion
Abundant acid hydrolases
Myeloid Dendritic Cells: Antigens
Major histocompatibility complex class II
Co-stimulatory molecules
CD11c
CD8 $\alpha^{+/-}$
DEC205
Dendritic cell-specific ICAM-grabbing non-integrin (DC-SIGN)
Dendritic cell-lysosome-associated membrane protein (DC-LAMP)
Other properties
Activation of naive CD4 T lymphocytes
Plasmacytoid Dendritic Cells: Antigens
CD123
B220
Lectin-like receptors (SIGLEC H)
Other properties
In vitro growth by flt-3 ligand
Osteoclasts
CD68
Tartrate-resistant acid phosphatase (TRAP)
Calcitonin receptor
$\alpha\beta 3$
Vacuolar H ⁺ ATPase
Proteinase K
Resorption of living bone

Note: Marker expression varies, depending on cell localization, maturation, and activation. Some markers also are present on other myeloid cells (e.g., polymorphonuclear neutrophils) and on selected endothelial cells. Structures and functions of receptor antigens are described elsewhere in this chapter.

characterization of additional receptors and markers; one example is the EGF-TM7 family of leukocyte receptors illustrated in Figure 10-3.³⁰ Although the F4/80 antigen has been extremely useful as a differentiation marker in the mouse, the human counterpart (EMR1) has not been of comparable value, showing a predilection for eosinophils. EMR2, a related human myeloid cell receptor, is a useful marker, however, expressed by many tissue mononuclear phagocytes; it binds chondroitin sulfate proteoglycans broadly present in connective tissue and has been implicated in leukocyte adhesion, migration, and activation.³¹

In joints, a resident synovial macrophage population is present, and recruited monocytes and macrophages are prominent in inflammatory, autoimmune, and infectious diseases, together with DCs and other myeloid and lymphoid cells. These resident and recruited mononuclear phagocytes have not yet been attributed to particular monocyte subsets. These may not be the same monocyte subpopulations that give rise to resident and recruited mononuclear

Figure 10-3 Myeloid cell antigens of the EGF-TM7 family. These G protein–coupled receptor (GPCR)-related receptors have a large extracellular domain consisting of multiple epidermal growth factor (EGF) modules. The F4/80 antigen, an excellent marker for mouse macrophages, has been implicated in peripheral tolerance.³⁵ The human orthologue EMR1 is a marker for human eosinophils. EMR2 is not expressed in the mouse but is present on human monocytes, macrophages, immature myeloid dendritic cells, and activated polymorphonuclear neutrophils. It is a useful surface marker for macrophages in tissues, including rheumatoid arthritic joints. CD97, expressed on myeloid cells and selected non-myeloid cells, is a receptor for the complement regulatory protein, CD55.⁹⁶ EMR2 and CD97 bind chondroitin sulfate B.³¹

phagocytes in other tissues and in response to different pathologies.

MOBILIZATION OF MONONUCLEAR PHAGOCYTES

Similar to other white blood cells, mononuclear phagocytes are distributed in intravascular and extravascular compartments, sharing common mechanisms of mobilization but also displaying distinct features among themselves and compared with other cell types. Exit from the bone marrow is controlled constitutively and on demand, but this process is not well understood, except for the role of chemokine receptors, such as CCR2 (ligands MCP1 through MCP4).³² What determines differentiation into the mature macrophages that form part of the stromal microenvironment in bone marrow is unknown; one possibility is re-entry of circulating monocytes from blood to bone, as for osteoclasts. Apart from the circulating pool of monocytes, many mature macrophages adopt a sinusoidal distribution in liver (Kupffer cells) and in selected lymphoid and endocrine organs. These cells are distinct from, but share endocytic properties with, sinusoidal endothelial cells. The constitutive exit through vascular endothelium to become tissue macrophages and DCs is not understood, whereas induced mobilization is well characterized, sharing many features with polymorphonuclear neutrophils.

Figure 10-4 summarizes stages and molecules implicated in monocyte egress. Although most monocytes exit the microvasculature by diapedesis between endothelial cells, evidence of an alternative transcytotic mechanism is

Figure 10-4 Stages and molecular interactions implicated in monocyte recruitment by inflammatory stimuli. Diapedesis of monocytes shares features with polymorphonuclear neutrophils.

present, as for lymphocytes. The roles of L-selectin, $\beta 2$, and other integrins, the immunoglobulin superfamily molecule CD31, and CD99 have been established by analysis of genetic deficiencies in humans and mice,³³ and by the use of monoclonal antibodies against these³⁴ and other defined adhesion molecules, such as vascular cell adhesion molecule-1 (VCAM-1) and very late activation antigen-4 (VLA-4). Endothelial cell ligands implicated in monocyte adhesion include fractalkine, a tethered chemokine; other chemokines may be presented by glycosaminoglycans.

The subsequent migration and fate of mononuclear phagocytes in tissues differ strikingly. Although many resident macrophage and DC subpopulations in tissues are well characterized,^{7,35} the origins of several functionally specialized cell types related to this overall lineage remain unclear.³⁶ Macrophages become sessile but can be induced by inflammatory stimuli to migrate to draining lymph nodes and remain there, without re-entering the circulation. Immature DCs respond to antigenic and inflammatory stimuli by migrating to draining lymphoid tissues, thereby transporting antigens for presentation to lymphocytes. The subcapsular sinus macrophages of lymph nodes have been implicated in trapping of DC antigen transported by afferent lymph³⁷ (Figure 10-5). DC maturation is accompanied by major changes in DC properties (Figure 10-6 and Table 10-2). DCs become highly mobile and express a range of chemokine and adhesion receptors. Entry of myeloid DCs and tissue macrophages into lymphatics is less well understood but may involve interactions with the mannose receptor. As a result, DCs can present exogenous antigens and self-antigens to CD4 T lymphocytes to activate or tolerize their responses. Although in vitro systems are widely used to generate DCs by cultivation of monocytes or bone marrow precursors in cytokine-supplemented media (GM-CSF, with or without IL-4), their properties may not correspond to those of DC populations in vivo.

Mononuclear phagocytes use integrins and receptors for extracellular matrix such as CD44, regulating the dynamics of their adhesion and migration. Osteoclast adhesion to

bone depends on $\alpha v \beta 3$ and possibly other adhesion molecules implicated in podosome attachment. Plasma membrane receptors such as CD97 and EMR2, members of the EGF-TM7 family, and TREM-1,³⁸ an immunoglobulin superfamily molecule with an immunotyrosine activation motif (ITAM)-based activation motif (see later), regulate myeloid cell effector functions and adhesion and migration within extravascular tissue compartments.

Monocytes recruited to tissues by poorly degradable foreign materials or by selected microbial pathogens or parasites form granulomas, organized structures rich in macrophages, incorporating other myeloid and lymphoid cells and fibroblasts and extracellular matrix. Pathogen-induced granuloma formation³⁹ depends on adhesion molecules such as CR3, a $\beta 2$ integrin, TNF, and chemokine receptors such as CCR4; granuloma macrophages express abundant secretory products such as lysozyme⁴⁰ and proinflammatory cytokines. Characteristic morphologic evidence of macrophage differentiation in granulomas includes epithelioid cell and multinucleated giant cell formation, such as with *Mycobacterium tuberculosis* infection. Giant cells arise by monocyte recruitment and macrophage fusion, rather than by impaired cytokinesis.^{41,41a} Cytokines such as IL-4 and IL-13, acting through a common receptor chain, and GM-CSF promote macrophage fusion. Foreign surfaces including biomaterials also can play a role in granuloma formation, and chemokine receptors have been implicated in the induction of foreign body-induced giant cells.

The surface molecules involved in these examples of macrophage homokaryon formation and the functional significance of induced fusion are still poorly understood. By contrast, multinucleation in osteoclasts is a physiologic process, dependent on M-CSF and RANK ligand, and several plasma membrane (CD44, CD9, TREM-2, DC-STAMP) and intracellular (c-src, c-fos) molecules have been implicated in this differentiation process. Multinucleation is thought to favor efficient localized resorption of bone. Osteoclasts become polarized for secretion and display highly active plasma membrane ruffling. Interactions with

Figure 10-5 Positioning of dendritic cells (DCs) within lymphoid tissues. Blood-derived monocytic precursors enter skin and mucosal peripheral tissues and differentiate into Langerhans cells within epithelia and into other immature DCs. When established, Langerhans cells turn over independently from bone marrow–derived cells⁴² (e.g., after ultraviolet irradiation). On exposure to stimuli (e.g., foreign antigens, local infections) and constitutively (after uptake of apoptotic cells, such as in the gastrointestinal tract), DCs undergo maturation, upregulate CCR7, and enter afferent lymphatics and secondary lymphoid tissues, where they interact with CD4 T lymphocytes. CD4 T lymphocytes become activated, interacting with B cells or CD8 T lymphocytes, and re-enter blood, homing to peripheral sites. DCs also are able to interact with innate lymphocytes and natural killer cells. Follicular DCs in B cell areas have a distinct, poorly defined bone marrow origin, express novel antigenic markers, and are able to capture immune complexes through complement activation. Plasmacytoid DCs have a distinct interfollicular location and express markers of a myeloid and a lymphoid nature. (Courtesy R. Steinman.)

Figure 10-6 Dendritic cell (DC) maturation. In the steady state, immature DCs are actively endocytic, capturing antigens efficiently through pattern recognition receptors. In response to a range of exogenous and endogenous stimuli, they translocate major histocompatibility complex class II to the surface, express a range of co-stimulatory molecules and secretory products, and become efficient antigen-presenting cells. As a result, DCs control adaptive immunity or induce tolerance. TNF, tumor necrosis factor. (Courtesy R. Steinman.)

Table 10-2 Maturation Markers for Human Monocyte–Derived Dendritic Cells

	Immature	Mature
Enhancer/Co-stimulatory Molecules		
CD80 (B7-1)	Low	High
CD86 (B7-2)	Low	High
CD83		De novo
EMR2 (CD312)	High	Moderate/low
Antigen Uptake		
FcγRII	High	Low
Signaling		
CD40	Low	High
CXCR4	Low	High
CCR5	High	Low
CCR6	High	Low
CCR7	Low	High
Antigen Presentation		
HLA-DR (major histocompatibility complex class II)	Moderate	High
HLA-DQ (major histocompatibility complex class II)	Moderate	High
CD1a	High	Low
Others		
DC-SIGN (CD209)	High	Low
CD14	High/moderate	Negative
CD123 (IL-3R)	Low	High

Note: In addition to the listed antigens and antigen-presenting cell functions, dendritic cell production of, and response to, other growth factors, chemokines and cytokines, microbial products, and immune complexes varies during maturation and activation in vitro. Validation in vivo is incomplete.

osteoblasts; local cytokines, such as osteoprotegerin; and circulating hormones, including calcitonin, parathormone, and vitamin D metabolites regulate their gene expression and function, as is discussed in Chapter 4. Vitamin D receptors also modulate the function of macrophages and DCs.

The turnover of different mononuclear phagocytes varies, depending on their activation status and tissue localization.⁴² Resident macrophages can live for weeks or months, whereas inflammation reduces survival to hours or days. DCs are relatively short-lived cells; osteoclast turnover *in vivo* has not been studied in detail. The role of apoptosis in mononuclear phagocyte turnover is poorly characterized, in contrast to that in polymorphonuclear neutrophils, but cell survival is regulated by growth factors such as M-CSF and by interactions with neighboring cells and pathogens.

RECOGNITION

In the past decade, emphasis on the problem of immune recognition has shifted to a considerable extent from somatically rearranged receptors for peptide, on lymphocytes, to germline-encoded receptors on myeloid antigen-presenting cells (APCs).⁴³⁻⁴⁵ Previous studies on myeloid cells focused on well-known opsonic receptors for antibody (Fc receptors) and complement (complement receptor). The concept of direct pattern recognition receptors for conserved structures on microbes provided an impetus to studies on innate immunity, reinforced by the discovery of TLRs. More recently, investigation of numerous NTRs, including a range of lectin-like recognition molecules and of scavenger receptors, markedly enhanced knowledge of the recognition repertoire.¹⁷ Finally came the discovery of cytosolic recognition proteins, the NLR, RIG-I families, and AIM2,⁴⁶ implicated in genetic and microbially induced hyperinflammatory syndromes, Crohn's disease, and nucleic acid sensing.

These molecules are mainly, although not exclusively, expressed by macrophages and DCs and play an important role in immune responses to foreign or modified host ligands, resulting in inflammation and autoimmunity. Given the complexity of microbial and cellular particulates compared with discrete soluble ligands, different receptors collaborate and synergize with one another to activate or inhibit subsequent APC responses. The original distinction drawn between pattern recognition receptors for exogenous, so-called pathogen-associated molecular patterns and for endogenous, host-derived ligands has been eroded to some extent because individual receptors are able to bind both types of ligand,⁴⁷ although their distinct cellular expression and signaling responses may account for discrimination by host APCs. In particular, recognition and uptake of apoptotic cells result in downregulation of macrophage effector molecules, as opposed to the proinflammatory effects induced by microbial ligands. The signaling pathways induced by other, modified host-derived ligands, such as oxidized lipoproteins and hyaluronates, are not well characterized.

This section summarizes selected receptor structures, indicates some of their ligands, and addresses briefly signaling and antigen processing pathways. Further details are provided in Chapter 18, which also illustrates interactions between humoral and cellular arms of the innate response.

Toll-Like Receptors

Key features of TLRs are illustrated elsewhere (see Chapter 18.^{48,49} TLRs consist of homodimers or heterodimers of transmembrane glycoproteins containing extracellular leucine-rich repeats (LRRs) and cytoplasmic Toll/IL-1 receptor (TIR) domains, similar to the intracellular domain of the IL-1 receptor, which contains extracellular immunoglobulin superfamily domains. TLRs are expressed on the surface of APCs or, in the case of TLR3, TLR7/8, and TLR9, on vacuolar membranes, contributing to proinflammatory and immunogenic signaling after “sensing” of cargo. Isolated TLRs do not bind ligands directly but collaborate with humoral factors and with other plasma membrane glycoproteins, as in the well-studied case of TLR4, the glycosyl phosphoinositide (GPI)-anchored CD14 receptor for the plasma lipopolysaccharide-binding protein and the membrane-associated molecule MD2.

Non-Toll-Like Receptors

NTRs constitute a variety of lectin-like,^{45,50} scavenger, and other plasma membrane glycoprotein nonopsonic receptors; selected examples are illustrated in Figures 10-7 and 10-8. They include type 1 and 2 transmembrane molecules, with C-type lectin or lectin-like, collagenous, or immunoglobulin superfamily domains. In addition, macrophages express sialic acid-binding receptors, members of the SIGLEC family.⁵¹ Table 10-3 summarizes known ligands and potential functions relevant to their role in homeostasis and immunity. Apart from direct recognition of selected self, modified self, and foreign structures, they play an important role in cell-cell and cell-matrix interactions; in phagocytosis and endocytosis; and in less well-understood processes, such as targeted delivery of antigens to peripheral lymphoid organs.⁵²

Receptors that promote rapid clearance of apoptotic cells, directly or after opsonization by complement and other extracellular proteins, are shown in Figure 10-9. More recent research has shown collaboration of different receptors at the cell surface,⁵³ regulating cellular responses. Other regulatory surface receptors include transmembrane molecules with tyrosine-based activating (ITAM) or inhibitory (ITIM) cytoplasmic motifs, for example, C-type lectin-like molecules, immunoglobulin superfamily members such as Fc receptors, discussed further subsequently, and receptor-ligand pairs that regulate macrophage activation (CD200/CD200R)⁵⁴ and phagocytosis (SIRP α and CD47) (Figure 10-10).⁵⁵

Complement Receptors

Complement receptors are heterogeneous receptors expressed by APCs (Figure 10-11) that mediate direct and lectin- and antibody-dependent binding of activated complement components and play a role in cell migration and phagocytosis and immune regulation.⁵⁶ The discovery of a novel complement receptor selectively expressed by Kupffer cells suggests that mononuclear phagocyte heterogeneity in complement receptor function provides evidence of tissue specificity for some macrophage subsets.⁵⁷ Genetic deficiencies in complement receptor expression and their ligands

Figure 10-7 Selected lectin-like receptors expressed by macrophages and dendritic cells (DCs). (See Table 10-3 for ligands.) These receptors play an important role in nonopsonic adhesion, cell-cell interactions, endocytosis, and phagocytosis. The cysteine-rich domain of the mannose receptor^{45,45a} has been postulated to play a role in transport of glycoconjugates to peripheral lymphoid organs for clearance or antigen-dependent activation of B lymphocytes.⁵² DEC205 has been used to show efficient targeting of antigens to DCs.⁹⁷ The ITAM-like motif of Dectin-1, the β -glucan receptor, is essential for myeloid cell responses to fungal particles, in collaboration with TLR^{50,53,81,98} and NLR. CTLD, C-type lectin domain.

Figure 10-8 Selected scavenger receptors. These non-TLRs consist of diverse structures and bind a range of microbial and endogenous ligands (see Table 10-3).^{100,101} They differ in regulation and expression, providing useful markers of macrophage activation (CD14, MARCO),^{14,99,101} heterogeneity (CD163, the scavenger receptor for clearance of haptoglobin-hemoglobin complexes),⁸⁷ and lipid homeostasis (SR-A, CD36, LOX-1).¹⁰⁰ Scavenger receptors such as MARCO can collaborate with TLRs in APC responses to microbes.¹⁰² APC, antigen-presenting cell; CTLD, C-type lectin domain; TLRs, Toll-like receptors.

Table 10-3 Ligands for Selected Nonopsonic, Non-Toll-like Receptors

Class	Receptor	Microbial Ligands	Endogenous Ligands	Function
Scavenger receptors	SR-A I/II	Gram-positive/gram-negative bacteria	Apoptotic cells	Phagocytosis
		Lipoteichoic acid	Modified low-density lipoproteins	Endocytosis
	MARCO	Lipid A	AGE-modified proteins	Adhesion
		Neisserial surface proteins	β -Amyloid	Foam cell formation
	CD36	Gram-positive/gram-negative bacteria	Marginal zone B lymphocytes	Adhesion
		Neisserial surface proteins	Uteroglobin-related protein	Phagocytosis
Lectins	Dectin-1	Diacylated lipopeptide from gram-positive bacteria	Apoptotic cells (with thrombospondin and vitronectin receptor)	Innate activation
		<i>Plasmodium falciparum</i> -parasitized erythrocytes	HDL	Uptake, exchange of lipids, macrophage fusion
	DC-SIGN	β -Glucan	Outer rod segments	Adhesion
		Mannosyl/fucosyl glycoconjugates including viruses (e.g., human immunodeficiency virus-1, dengue)	T lymphocytes (noncarbohydrate)	Fungal uptake and immunomodulation
	Mannose receptor CRD	ICAM 2/3 T lymphocytes	Lysosomal hydrolases	Adhesion
		Mannosyl/fucosyl glycoconjugates on bacteria, viruses, fungi, parasites	Thyroglobulin	Endocytosis
	Cysteine-rich domain	Ribonuclease	β -Amylase	Adhesion
	Fibronectin type II domain	Sulfated carbohydrates in marginal zone (spleen) and subcapsular sinus (lymph node)	Collagens	Antigen targeting
				Adhesion

Note: This table illustrates the dual recognition properties and diverse cellular functions of selected non-Toll-like receptors. For additional details, see references 45, 101, and 107-110.

AGE, advanced glycation end product; CRD, carbohydrate recognition domains (Ca⁺⁺-dependent); HDL, high-density lipoprotein; ICAM, intercellular adhesion molecule.

have provided insights into the pathogenesis of autoimmune disease and of rheumatic joint injury.⁵⁸ Complement deposition on follicular DCs has been implicated in the activation of B cell responses. Complement regulatory proteins are expressed by many cell types and APCs and play an important role in limiting cell activation. In addition, complement receptors collaborate with other receptors to modulate myeloid cell responses. Their signaling pathways are less well defined than those of Fc receptors.

Fc Receptors

APCs express diverse receptors for monomeric and complexed immunoglobulins regulating effector responses to antigens. Figure 10-12 illustrates the properties of human Fc receptors with activating or inhibitory motifs in their cytoplasmic tails. Fc receptor polymorphisms have been implicated in autoimmune human diseases such as systemic lupus erythematosus. Studies on genetically manipulated mouse models have led to considerable insights into the role of individual Fc receptors in immunopathogenesis. Fc receptors are able to cooperate with chemokine and other receptors. The nature and role of Fc-independent interactions of antibody with APCs are under investigation and include lectin-like recognition of sialylated⁵⁹ and mannosyl⁶⁰ residues.

Cytosolic Receptors

Identification of microbial peptidoglycan breakdown and other products as ligands for an intracellular family of LRR-containing cytosolic sensors that regulate caspase activation and IL-1 β secretion, especially in macrophages, provided a major impetus to this burgeoning field.^{2,17} Other chapters describe examples of NLRs and their role in hyperinflammatory syndromes, as well as RIG-I-like and other nucleic acid sensing receptors. NLRs and other cytosolic receptors participate in signaling pathways implicated in TLR-induced functions and play a major role in inflammasome activation, caspase-1 activation, and IL-1 and IL-18 release.

RIG-I and MDA-5 are members of the RIG-I-like receptor (RLR) RNA helicase family, found in macrophages and other myeloid cells, as well as in nonhematopoietic cells. They play a role in recognition of viral RNA, such as single-stranded RNA with 5'-triphosphate and/or double-stranded RNA. Although distinct, they share signaling features (e.g., recruitment by adapter IPS [also known as MAVS, CARDIF, or VISA] to the outer membrane of mitochondria) and activate transcription factors involved in type I interferon induction and antiviral immunity. RLR recognition of RNA is predominant in macrophages, cDCs, and fibroblasts, but pDCs utilize TLR preferentially.⁶¹ Gene deletion⁶² or silencing has shown that RIG-I modulates the generation and

Figure 10-9 Phagocytic receptors for apoptotic cell phagocytosis.¹⁰³ Macrophages (MØ) and immature myeloid dendritic cells (DCs) are the main immune cells involved in the clearance of apoptotic cells. They express broadly similar multiple receptors, which can bind directly or via opsonic soluble proteins (e.g., mannose-binding lectins [MBLs] to ligands). Phosphatidylserine (PtdSer) becomes exposed on the outer surface of the apoptotic cell, and a receptor for this ligand has been long sought. A new receptor (TIM4 and related TIM1) has been discovered on resident MØ, with specificity for PtdSer. Other MØ populations use MFGE8 (a milk fat globulin protein secreted by MØ) as an opsonin. Discrimination of nonself and altered self may involve combinations of different phagocyte receptors. Apoptotic cell uptake results in an anti-inflammatory response by MØ (e.g., release of TGF- β and PGE₂) and has been implicated in cross-presentation by DC. MFGE8, milk fat globule-EGF factor 8 protein; PGE₂, prostaglandin E₂; TGF, transforming growth factor; TIM, T cell immunoglobulin mucin. (From Savill J, Dransfield I, Gregory C, et al: A blast from the past: clearance of apoptotic cells regulates immune responses, *Nat Rev Immunol* 2:965–975, 2002.)

Figure 10-10 Surface receptors that, singly or as paired receptors, modulate macrophage responses. Illustrated are immunoglobulin superfamily and associated transmembrane molecules using ITAM or ITIM motifs to generate activating or inhibitory signals. DAP12 can associate with a range of other membrane molecules as a signaling partner in macrophages, dendritic cells, and natural killer cells.¹⁰⁴ Note the charged amino acid residues in transmembrane domains. CD200 and CD47, which are broadly expressed in tissues, generate inhibitory signals in macrophages via CD200R⁵⁴ and SIRP α .⁵⁵ In CD200 knockout mice, macrophages show spontaneous activation.⁹⁴ Macrophages themselves are induced by Toll-like receptor stimuli to express CD200.⁵⁴

Figure 10-11 Complement receptors and membrane regulators expressed by macrophages. CR1 is broadly expressed by nucleated cells, acting as a “sink” for activated complement; CR3 (CD11b/CD18), a phagocytic receptor for C3b-coated particles, and CR4 (CD11c/CD18) are β_2 integrins, which, together with LFA-1 (CD11a/CD18), mediate adhesion of myeloid cells to endothelium and extracellular matrix and migration. huCRig L and S are long and short forms of a newly described complement-binding receptor on Kupffer cells, which mediate uptake of opsonized bacteria.⁵⁷ CD55 and CD59 are glycosyl phosphoinositide (GPI)-anchored regulators of complement activation.

differentiation of granulocytes in the absence of virus infection, and that it is involved in phagocytosis of bacteria by LPS-stimulated macrophages, indicating broad function in innate immunity.⁶³

AIM-2 is a DNA-sensing cytosolic protein that triggers the NALP-independent inflammasome.⁴⁶ It contains an N-terminal pyrin domain and a C-terminal oligonucleotide

binding domain. It binds double-stranded DNA, recruits the inflammasome adapter ASC, and becomes localized to ASC-containing speckles, forming a pyroptosome and inducing pyroptotic cell death mediated by caspase-1. RNA silencing impairs DNA-induced maturation of IL-1 β in THP-1 human monocytic cells, abrogating caspase-1 activation by double-stranded DNA or *Vaccinia* infection. PYHIN

Figure 10-12 Human Fc receptors. Myeloid cells express a range of classic Fc receptors that initiate a variety of cellular responses, including phagocytosis, antibody-dependent cell-mediated toxicity, antigen presentation, respiratory burst, and release of inflammatory mediators. Immunoglobulin subclasses are bound by extracellular domains; signaling via cytoplasmic ITAM or ITIM is mediated by associated membrane-spanning polypeptides. Activation and inhibitory receptors usually are co-expressed on the cell surface and function in concert, determining the magnitude of effector cell responses. A range of Fc receptor-like molecules (immunoglobulin superfamily [IGSF] extracellular domains), with similar ITAM/ITIM cytoplasmic motifs, are mainly expressed by B or T/natural killer cells; they may regulate lymphocytic differentiation and responses.¹⁰⁵ GPI, glycosyl phosphoinositide; ITAM, immunotyrosine activation motif; ITIM, immunotyrosine inhibition motif.

proteins AIM-2 and IFI16 form a new family of innate DNA sensors, termed *AIM-2-like receptors* (ALRs).⁶⁴

Damage/Danger-Associated Molecular Patterns (DAMPs)

Host-derived molecules that activate TLR pathways and inflammasomes such as NLRP3 include nuclear and cytosolic proteins (e.g., HMGB1, S100), matrix components (hyaluronate), adenosine triphosphate (ATP), and uric acid. They are released by cell stress, especially necrosis, and contribute to the initiation and perpetuation of sterile and infectious inflammation. Other receptors include receptor for advanced glycation end products (RAGE) and possibly scavenger receptors, although ligands are promiscuous and often are poorly defined. The concept gained currency from work by Matzinger and colleagues.⁶⁵ Various hypotheses have been proposed for inflammasome activation, including K⁺ efflux, membrane pore formation, lysosome disruption and cathepsin release, and reactive oxygen species (ROS), which may be necessary but is not sufficient for caspase activation.⁶⁶

RESPONSES AND MODULATION

This section summarizes some of the major cell biologic effects resulting in antigen processing and presentation by APCs. Other chapters address related topics, such as recognition of lipids by CD1 and intracellular trafficking of related molecules.

Phagocytosis and Endocytosis: Antigen Processing

The vacuolar apparatus of APCs is illustrated schematically in Figure 10-13.^{67,68} Internalization of the plasma membrane

results in phagosome/endosome formation, with progressive acidification and digestion, depending on delivery of vesicles and their hydrolytic contents. Membrane and receptors are recruited, modified by maturation, and are retrieved by recycling. Further fusion with Golgi-derived vesicles and primary lysosomes yields phagolysosomes and secondary lysosomes, reaching a pH of approximately 5.5 to 6.0. Depending on the bulk of plasma membrane internalized and the size of the particle, the uptake process involves cytoskeletal components⁶⁹ and small guanosine triphosphatases (GTPases) and docking machinery. Guanosine triphosphate (GTP) hydrolysis serves as an important mechanism for controlling intracellular membrane traffic and coupling to the cytoskeleton. Cytokines such as interferon- γ can have a major effect on activation and relocation of GTP-binding proteins, contributing to host cell-pathogen interactions.⁷⁰

Proteomic analysis of isolated phagolysosomes has revealed more than 600 constituents, classified according to the source of the membrane and various putative functions.⁷¹ Although most membrane constituents are derived from the plasma membrane, descriptions of contributions from the endoplasmic reticulum have elicited considerable interest, along with different estimates of their extent.^{71,72} Another controversial aspect relates to the role of TLR engagement in enhancing the kinetics of the maturation process, a transcription-independent process.⁷³ Variations on this theme occur, depending on cell type and maturity, whether the extracellular cargo is microbial or host-derived, and whether the process arises by autophagy,⁷⁴ rather than heterophagy. The role of autophagy in cellular resistance to intracellular pathogens, such as *M. tuberculosis*, is receiving increasing consideration.^{75,76}

Immature DCs are actively endocytic and phagocytic but poor APCs, whereas mature DCs downregulate uptake but acquire highly efficient APC function.¹⁸ Changes associated

Figure 10-13 Schematic presentation of phagocytosis and endocytosis. Particulates are taken up by actin-dependent sequential maturation processes involving membrane fusion and fission, which intersect with the endocytic pathway at several stages. Cytosolic small guanosine triphosphatases (GTPases) (Rabs) determine organelle-specific interactions. Membrane is recycled to the plasma membrane with processed antigen (see Figure 10-14). Progressive acidification and delivery of lysosomal hydrolases result in terminal degradation. Compartment membranes express marker proteins such as LAMP1; the pan-macrophage CD68 antigen is associated with late endosomes and lysosomes.

Figure 10-14 Different antigen-processing pathways for the major histocompatibility complex (MHC) class I and class II molecules.¹⁰⁶ **A**, MHC class I molecules present peptides that are derived primarily from endogenously synthesized proteins of self or pathogen origin. These proteins are degraded into peptides by the proteasome and are transported through the transporters of antigen-processing (TAP) molecules into the endoplasmic reticulum for loading on MHC class I molecules. **B**, MHC class II molecules present proteins that enter the cell through the endocytic route. During maturation of MHC class II molecules, they are prevented from binding to endogenous antigens in the endoplasmic reticulum by association with the invariant chain (Ii). Invariant chain–MHC class II complexes (MHC II-Ii) move through the Golgi to the MIIC/CIIV compartment, where the invariant chain is degraded to class II-associated invariant-chain peptide (CLIP). CLIP is removed from the CLIP–MHC class II (MHC-CLIP) complexes and is exchanged for antigenic peptide. **C**, Dendritic cells can endocytose antigens from other cells and cross-present them to CD8⁺ cytotoxic T lymphocytes. In most cases, these antigens also are processed into the MHC class II presentation pathway for recognition by CD4⁺ helper T cells. CIIV, MHC II vesicles; MIIC, MHC II loading compartment. (From Heath WR, Carbone FR: Cross-presentation in viral immunity and self-tolerance, *Nat Rev Immunol* 1:126–134, 2001.)

with DC maturation and antigen presentation are illustrated in Figures 10-7 through 10-14. Pathogenic intracellular organisms vary in their subversion of the aforementioned process, interfering with different stages, such as cytosolic signaling mechanisms, fusion, or acidification, and in selected cases, inducing a novel membrane composition.⁷⁷ Organisms can replicate in immature or mature compartments, or can translocate their genome to the cytosol by acid-induced envelope fusion or by disruption of the vacuolar membrane.

Signaling

The best-characterized signaling responses in macrophages include the TLR,⁷⁸ type I interferon,⁷⁹ and Fc receptor-induced pathways.⁸⁰ The various signaling cascades are complex, interact with one another, and result in phosphorylation/dephosphorylation, formation of cytosolic protein complexes, and activation of signaling proteins such as nuclear factor κ B (NF κ B), which enter the nucleus to regulate transcription. In the case of TLR-dependent sensing, a restricted number of adapters, such as MyD88, TIRAP-MAL, and TRIF, channel the flow of information into the cell. Emerging evidence suggests that NTR-induced signaling (e.g., by the β -glucan receptor [Dectin-1] cytoplasmic ITAM-like motif)⁵⁰ collaborates with TLR and NLR signaling pathways, with differential involvement of syk and

CARD9⁸¹ in effector responses in different mononuclear phagocytes. Distinct but interlinked pathways involve interferon regulatory factors as part of an amplification pathway with broader immunoregulatory functions than antiviral responses alone. A more recently defined cytosolic specialized antiviral pathway involves interaction with mitochondrial components.⁶⁴ Cell surface or intracellular proteins serve as negative regulators, as exemplified by members of the SOCS family.

Figure 10-14 illustrates the pathway by which effector response-derived antigens are transported to the cytosol during synthesis, are processed in proteasomes, and become associated with MHC class I molecules for presentation at the cell surface. Effector response chaperones, such as heat shock protein, may contribute to the surface delivery of antigens. The inflammasome is another example of a multiprotein assembly within the cytosol by which NLRs bring about IL-1 activation.

Several of the processes already described involve proteolytic enzymes, including cathepsins and caspases, and lipid-interacting chaperones. The ubiquitin pathway provides an important mechanism for cytosolic degradation of proteins. In addition, vacuolar H⁺ ATPases contribute to acidification in different mononuclear phagocytes, especially relevant to osteoclast function. Comparison and further elucidation of the coupling between extracellular and intracellular signaling pathways in macrophages, DCs, and osteoclasts would be of great interest.

Efferent Pathways: Gene Expression and Secretion

The complex responses of different mononuclear phagocytes to intrinsic and extrinsic stimuli have been defined by microarray studies and, in some cases, by protein and functional analyses. Although the major differentiation pathways (macrophages, immature and mature DCs, and osteoclasts) involve selective, stereotypic changes in gene expression, the extensive heterogeneity and plasticity of phenotypes characterizing these cells *in situ* have begun to be appreciated only more recently.⁴ Macrophages are known to express numerous nuclear receptors,⁸² which undergo dynamic changes depending on cellular differentiation and the microenvironment, as well as epigenetic histone modification⁸³ and micro-RNA expression. Exposure to particular cytokines, hormones, and other stimuli, such as microbial antigens and immune complexes, modulates gene expression profoundly and selectively and induces posttranscriptional and posttranslational changes. Through alternative splicing, glycosylation, and poorly characterized protein modifications (e.g., methylation and acetylation of nuclear

and cytoplasmic macromolecules), this exposure provides different mononuclear phagocytes with extensive diversity in adaptation and function.

Table 10-4 provides a partial list of macrophage secretory products; these include low-molecular-weight metabolites (oxygen, nitrogen, and lipid-derived) implicated in inflammation and its resolution⁸⁴ and in antimicrobial responses; other products include proinflammatory and anti-inflammatory cytokines and neutral proteinases. The cell biology of the secretory pathway in macrophages has only begun to be studied. The differential effect of T helper type 1 and T helper type 2 cytokines on nitric oxide production versus its destruction is thought to be relevant to microbicidal mechanisms versus repair.⁴ The secretory activity of DCs and osteoclasts is less defined except with regard to their specialized functions (e.g., lymphocyte activation, bone remodeling).

Table 10-5 shows a classification of characteristic effects induced by prototypic activating and inhibitory stimuli. It is convenient to distinguish the phenotype of mononuclear phagocytes stimulated by an innate stimulus, including exposure to microbial products such as lipopolysaccharide;

Table 10-4 Selected Products Secreted by Macrophages

Proteins	Product	Comment
Enzymes	Lysozyme Urokinase-type plasminogen activator Collagenase Elastase Metalloproteinases Complement Arginase Angiotensin-converting enzyme Chitotriosidase	Bulk product Regulated by inflammation Regulated by inflammation Regulated by inflammation Also inhibitors All components and regulators Alternative activation Induced glucocorticoids, granulomas Gaucher's disease, lysosomal storage disease
Inhibitors	Acid hydrolases TIMP	All classes (mainly intracellular)
Chemokines	Many C-C, C-X-C, CX3C (e.g., MCP, RANTES, IL-8)	Initiate short- and long-term recruitment of myeloid and lymphoid cells
Cytokines	IL-1 β , TNF, IL-6, IL-10, IL-12, IL-18, IL-23 Type I interferon	Proinflammatory and anti-inflammatory Also antagonists (e.g., IL-1Ra) Autocrine and paracrine amplification
Apolipoproteins	Apolipoprotein E	Local source, bone marrow origin after adoptive transfer
Growth/differentiation factors	TGF- β M-CSF GM-CSF FGF PDGF VEGF	Also other family members (activins) Myeloid growth and differentiation Fibrosis Repair Angiogenesis
Opsonins	Fibronectin, pentraxin (PTX3)	Additional uncharacterized receptor on macrophages
Soluble receptors	Mannose receptor	Soluble mannose receptor
Cationic peptides	Defensins	Subpopulations and species variation
Lipids	Procoagulant Arachidonate metabolites Prostaglandins Leukotrienes Thromboxanes Resolvins	Initiation of clotting Proinflammatory and anti-inflammatory mediators
Metabolites	Reactive oxygen intermediates Reactive nitrogen intermediates Hemoglobin breakdown (bile pigments) Iron, vitamin B ₁₂ binding protein Vitamin D metabolites	

Note: For additional details, see references 111 and 112.

FGF, fibroblast growth factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; MCP, monocyte chemotactic protein; M-CSF, macrophage colony-stimulating factor; PDGF, platelet-derived growth factor; RANTES, regulation upon activation normal T cell expressed and presumably excreted; TGF, transforming growth factor; TIMP, tissue inhibitor of metalloproteinase; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor.

Table 10-5 Immunomodulation of Macrophage Phenotype

Stimulus	Category	Markers	Function
Microbial (bacterial)	Innate Activation	Induction of MARCO Co-stimulatory molecules CD200	Enhanced phagocytosis Antigen presentation Inhibition (CD200R)
Interferon- γ	Classic activation	Induction of MHC II	Cell-mediated immunity/delayed-type hypersensitivity
		Potentialization of innate markers TNF iNOS induction NADPH, respiratory burst LGP47 induction	Proinflammatory Antimicrobial (NO), signaling Host defense, inflammation Association with phagosome/intracellular pathogen killing
IL-4/IL-13	Alternative activation Upregulation	Downregulation of MR Modulation of FcR expression Proteasomal composition Enhanced MR Induction of arginase Induction of YM1 FIZZ1 (mouse) Induction of CCL17 (MDC) and CCL22 (TARC) Fusion, giant cell formation CD23 (FcRe)	Unknown Antigen presentation Endocytosis Humoral immunity Th2 responses Allergy, antiparasitic Immunity
IL-10 TGF- β	Deactivation	Downregulation of MHC II Downregulation, proinflammatory NO and ROI	Repair/fibrosis
Immune complexes	Modified activation	Selective IL-12 downregulation IL-10 induction	
Glucocorticoids	Deactivation	CD163 induction Monocyte recruitment downregulated ACE induction Stabilin induction	Anti-inflammatory Homeostatic clearance Hemoglobin-haptoglobin complexes

Note: For additional details, see references 4, 16, and 113.

ACE, angiotensin-converting enzyme; FcR, Fc receptor; IL, interleukin; iNOS, inducible nitric oxide synthase; LGP47, lysosomal glycoprotein; MARCO, macrophage scavenger receptor; MDC, macrophage-derived chemokine; MHC, major histocompatibility complex; MR, mannose receptor; NADPH, nicotinamide adenine dinucleotide phosphate-oxidase; NO, nitric oxide; ROI, reactive oxygen intermediates; TARC, thymus and activation-regulated chemokine; TNF, tumor necrosis factor.

by a classic immune activating cytokine such as interferon- γ ; and by IL-4/IL-13 induction of an alternative activation pathway⁴ by IL-4/IL-13. Other stereotypic responses are induced by immune complexes that selectively modulate IL-12/IL-10 expression.⁸⁵ Innate and immune cytokine stimuli are able to potentiate one another.

Conversely, deactivating stimuli such as IL-10 and transforming growth factor (TGF)- β and glucocorticosteroids⁸⁶ induce their own distinctive patterns of gene expression. Upregulation of CD163, a hemoglobin-haptoglobin scavenger receptor, is a striking example of glucocorticosteroid-enhanced endocytic function.⁸⁷ Stimulation of the vagus nerve attenuates macrophage activation by activating the Jak2-STAT3 signaling pathway.⁸⁸ Deactivation of macrophages plays a critical role in limiting proinflammatory activation induced by cytokines (e.g., interferon- γ) and opsonic (FcR) and nonopsonic stimulation (TLR, NLR, inflammasomes), acting via a range of signal transduction pathways and naturally occurring antagonists. Deactivation of macrophages is a particular feature of phagocytic uptake of apoptotic cells (see Figure 10-9) thought to be mediated by TGF- β , prostaglandin (PG)E₂, and IL-10, which also inhibit the generation of reactive nitrogen and oxygen species. The resolvins and protectins derive from the omega-3 fatty acids eicosapentanoic acid (EPA) and docosahexaenoic acid (DHA) produced by the cyclooxygenase (COX)-2 pathway, especially in the presence of aspirin.

They inhibit production and recruitment of leukocytes to sites of inflammation and counteract pain.⁸⁹

Plasma membrane signals to deactivate macrophages arise from trans-ligation of CD200 (expressed by many cells, including innate-activated macrophages) and its signaling immunoglobulin superfamily (IGSF) counterpart CD200R, expressed selectively by macrophages.⁵⁴ Another inhibitory receptor pair consists of SIRP α and CD47⁵⁵; cytosolic inhibitors include the SOCS proteins.²⁰ These extracellular mediators and poorly defined interactions with surface expressed molecules make the different APCs reciprocally interactive with other immune cells (helper and regulatory CD4 T cells, CD8 T cells, natural killer cells, and natural killer T [NKT] cells) and with nonhematopoietic cells such as fibroblasts, epithelium, and neurons. Induced responses on macrophages include altered MHC class II and co-stimulatory molecule expression, marker antigens involved in cellular interactions, phagocytosis and antigen presentation, and altered secretion. As a result, different mononuclear phagocytes are able to modulate their interactions with CD4 T lymphocytes, with endothelial and other cell types, with extracellular matrix, and with bone to induce trophic and cytostatic/cidal and catabolic effects.

Human inborn errors or defects in macrophage responses to intracellular pathogens such as mycobacteria⁹⁰ have validated studies on cell activation in the mouse. The immunosuppressive effects of macrophages in immune tolerance

to an allogeneic fetus have been ascribed to induction of indoleamine-2,3-dioxygenase, which catabolizes the essential amino acid, L-tryptophan.⁹¹ Macrophage products act mainly locally but also can have profound systemic effects, regulating metabolic and regulatory responses within the host. These effector programs and products provide targets for pharmacologic intervention.

Relevance to Selected Rheumatic Diseases

Although the different mononuclear phagocytes have been addressed as part of a general host homeostatic system, there are good examples in human rheumatic diseases and in animal models of arthritis in which these cells play a role in the local initiation or effector phase of the pathology. Primary defects in osteoclast differentiation and function contribute to osteopetrosis or, if overactive, osteoporosis. I have referred to autoinflammatory syndromes and the newly discovered cytosolic receptors. Gout might also fall in this category because uric acid crystals provide a metabolic stimulus for inflammasome activation. Macrophages play a role in the pathogenesis and complications of osteoarthritis, including the response to foreign implants. DCs and macrophages play a part in the induction and effector mechanisms of autoimmune arthritis, in concert with T lymphocytes and B lymphocytes and their products, immune complexes, and complement. The catabolic role of TNF, IL-1, neutral proteinases, reactive oxygen radicals, and arachidonate metabolites is well known. Less well appreciated are the trophic interactions of macrophages with fibroblasts through production of TGF- β , growth and angiogenic factors, and modulation by alternative activation pathways.⁹² Type I interferons, produced by macrophages and other cells, play an important amplification role in autoimmune inflammation (e.g., systemic lupus erythematosus [SLE]).

Although animal models may not mimic the natural diseases in humans, more recent examples suggest that APC membrane receptors involved in recognition of modified self and foreign microbial ligands could be relevant to arthritis—in streptococcal rheumatic disease and in exacerbation of recurrent arthritis by zymosan in T cell transgenic mice, acting via Dectin-1, the APC receptor for β -glucans.⁹³ In addition, inhibitory plasma membrane receptor interactions (CD200/CD200R) limit macrophage activation and collagen-induced murine arthritis.^{54,94} Impaired clearance of apoptotic cells by (uncharacterized) C1q receptors of mononuclear phagocytes may contribute to autoimmune diseases such as lupus.⁵⁸ Finally, macrophages could contribute to wider connective tissue disorders, such as scleroderma, because they are able to regulate fibroblast and matrix synthesis and turnover through metalloproteinases and TGF- β ; dysregulation of these pathways has been neglected as a pathogenetic mechanism in these metabolic diseases.

ISSUES FOR FURTHER INVESTIGATION

As we take stock of how increasing knowledge of mononuclear phagocyte biology has affected pathogenesis and therapy of rheumatic diseases, additional questions arise regarding basic mechanisms and new selective targets. Treating macrophages, DCs, and osteoclasts as specialized

forms of a unitary mononuclear phagocyte family helps to bring out their common and distinctive properties. Selective expression and signaling pathways of pattern recognition receptors by macrophages and DCs are still poorly characterized—regulation of TLR signaling has already received considerable attention as a possible drug target. Discrimination of microbial and host-derived ligands may account for mimicry and autoantigen cross-reactivity, but mechanisms for regulating homeostatic and tolerogenic responses are still unclear.

On the effector side, success with anti-TNF monoclonal antibodies suggests that targeting of individual effector molecules can succeed, especially when these are expressed at the cell surface and are proximal in cascade reactions. The impact of anti-TNF therapy on macrophage functions and mechanisms for resistance to TNF blockade are poorly understood. The role of inhibitory/activating pairs of surface molecules as modulators of APC pathways is unexplored and is likely to move center stage. One neglected aspect of differentiation and function for osteoclasts and granuloma macrophages is the mechanism of fusion and the possible functional significance of multinuclear giant cell formation. Basic knowledge is still lacking and may provide useful insights into the pathogenesis of metabolic bone diseases and enhanced perception of links with the immune system, both innate and adaptive.

Although powerful tools of mRNA and proteomic analysis and gene silencing by RNAi inhibition have become available, the heterogeneity and complexity of mononuclear phagocytes in human tissues, especially at early stages of disease, need improved characterization in situ and at different sites. Much remains to be learned concerning trophic processes and repair and their relationship to resolution of inflammation and fibrosis. These involve cell-cell interactions that are poorly understood but are increasingly amenable to investigation.

Acknowledgments

The author thanks Christine Holt and Amelia Molloy-Bland for preparation of the manuscript and present and past members of his laboratory for help with illustrations. Work in the Gordon Laboratory has been supported by the Medical Research Council, United Kingdom; the Wellcome Trust; the Arthritis Research Campaign; and the British Heart Foundation.

KEY POINTS

Neutrophils are myeloid-lineage cells characterized by the presence of granules containing enzymes and other potentially toxic agents involved in host defense.

Neutrophils are short-lived, terminally differentiated cells that exist primarily in the bloodstream, where they participate in host surveillance of foreign organisms.

Neutrophils function in acute inflammation and provide an essential defense against acute bacterial infections; abnormalities of neutrophil function are uncommon and impair ability to respond to life-threatening infections.

A key function of neutrophils is to ingest foreign particles such as bacteria and degrade them through activation of proteases, activation of other antibiotic molecules, and generation of toxic oxygen radicals.

Neutrophils play a role as a major inflammatory cell in many rheumatic conditions and may be attracted into tissues by noninfectious stimuli such as activated complement components and lipid inflammatory mediators.

INTRODUCTION: POLYMORPHONUCLEAR LEUKOCYTES

Polymorphonuclear leukocytes constitute a family of hematopoietically derived cells that share the feature of a multi-lobed nucleus. These leukocytes also share a property of possessing highly developed populations of intracytoplasmic granules, divisible into subsets and distinct between cell types. The presence of these granules permits the further designation of polymorphonuclear leukocytes as granulocytes. On the basis of the histochemical staining properties of their respective granules, three classes of polymorphonuclear leukocytes have been identified: neutrophils, eosinophils, and basophils. Neutrophil (polymorphonuclear neutrophil) granules stain with neutral dyes; the granules of eosinophils are most effectively stained with acidic dyes such as eosin, and basophil granules stain with basic dyes. In a standard polychromatic Wright stain of a peripheral blood smear, the cytoplasm of neutrophils, eosinophils, and basophils appears blue-pink (neutrophils), pink (eosinophils), and blue (basophils). These classes of polymorphonuclear leukocytes differ with respect to not only appearance but also biochemistry and function. Polymorphonuclear leukocytes constitute an important part of the organism's system of innate immunity: Their responses to foreign organisms, antigens, or both are preprogrammed and do not depend on prior exposure to the particle.

Neutrophils

JOSE U. SCHER • STEVEN B. ABRAMSON •
MICHAEL H. PILLINGER

NEUTROPHILS

Neutrophils are the body's first line of defense against foreign invaders and constitute the major cell type involved in acute and some forms of chronic inflammation. The importance of neutrophils in bacterial defense is illustrated by patients who have hereditary defects in neutrophil function and are prone to repeated and often life-threatening infections. Neutrophils are the most prevalent leukocyte in the bloodstream, typically constituting greater than 50% of all bloodstream leukocytes. During bacterial infection, the percentage of neutrophils may increase to 80% or more. In contrast, tissue concentrations of resting (inactive) neutrophils seem to be quite low. Neutrophils may be considered surveillance cells—sweeping through the bloodstream scanning for infections or other inflammatory events. The capacity of neutrophils to destroy foreign organisms is matched in some circumstances, however, by a capacity for host tissue destruction.

Neutrophil Myelopoiesis and Clearance

The neutrophil majority in the bloodstream is duplicated in the bone marrow, where 60% of hematopoietic capacity may be dedicated to neutrophil production. Daily, 10^{11} neutrophils are released into the bloodstream. Neutrophil development in the marrow takes about 14 days, originating from the hematopoietic stem cell. Stem cells fated to become neutrophils first differentiate into myeloblasts, which retain the capacity to develop into eosinophils, basophils, and neutrophils. Subsequent differentiation leads to the neutrophilic promyelocyte, a dedicated precursor of the neutrophil, and proceeds through the stages of neutrophilic myelocyte, metamyelocyte, band cell, and mature neutrophil. At the metamyelocyte stage, neutrophil mitosis ceases, whereas neutrophil development and organization of granules continue. Neutrophils are terminally differentiated; they neither divide nor alter their gross phenotype after their release from the marrow.

Given the origin of neutrophils in a pluripotent stem cell, as well as the precise phases of their development, the mechanisms regulating neutrophil differentiation are of considerable interest. Although incompletely understood, studies have emphasized the role of a particular complement of transcription factors and cytokines that seem to direct the early cells toward neutrophil development. Several myeloid factors are necessary for the transcriptional regulation of neutrophils including LEF-1, CCAAT enhancer binding proteins α and ϵ (C/EBP α and C/EBP ϵ), and GFI-1. Principal among the cytokines regulating granulopoiesis is granulocyte colony-stimulating factor (G-CSF). G-CSF effects include induction of myeloid differentiation,

Figure 11-1 Resting and stimulated neutrophil morphology. **A** and **B**, Transmission (**A**) and scanning (**B**) electron micrographs of resting neutrophils. In **A**, note the multilobed nucleus and the rich population of granules. At least two populations of granules may be discerned: The larger, darker granules represent the primary (azurophilic) granules, whereas the smaller, slightly paler granules are predominantly secondary (specific) granules and may include a population of gelatinase granules (arrow indicates primary granule). In **B**, note the relatively smooth surface area with some membrane surface irregularities. **C** and **D**, Transmission (**C**) and scanning (**D**) electron micrographs of neutrophils 1 minute after stimulation with zymosan. The cellular diameter is enlarged, and the overall surface (plasma) membrane area is greatly increased. Most of the membrane contributing to the increased surface area is supplied via the fusion of internal granule membranes with the plasma membrane. In **C**, this fusion is apparent as the depletion of granules, leading to an appearance of empty vesicles (arrow indicates a partially depleted primary granule; clear circular areas represent fully depleted vesicles whose membranes are fused to the plasma membrane). In **D**, this fusion is apparent as the increase in plasma surface membrane extensions, known as *lamellipodia*. (Courtesy G. Weissmann, NYU School of Medicine.)

proliferation of granulocyte precursors, and release of mature neutrophils from the marrow.¹ Biologic effects of G-CSF are mediated through its receptor (G-CSFR or CD114), a member of the class I cytokine receptor family. Although other hematopoietic cytokines contribute to granulopoiesis in vivo (including granulocyte-macrophage colony-stimulating factor [GM-CSF], interleukin [IL]-6 and IL-3), their individual presence is not essential as demonstrated by knockout experiments.

Once mature, neutrophils exit the bone marrow through the tight-fitting pores of the sinusoidal endothelium and enter the circulation, a process called *transcellular migration*.² Neutrophils released from the marrow have a bloodstream half-life of approximately 6 hours and a tissue half-life only marginally longer. Neutrophil life spans may be modulated by soluble signals: when exposed to stimuli such as tumor necrosis factor (TNF) and Fas (CD95) ligand, neutrophils undergo apoptosis or programmed cell death.^{3,4} The high output and short half-life of neutrophils imply that neutrophil clearance mechanisms must exist. Recently, the SDF-1/CXCR4 signaling system has been implicated in neutrophil clearance. CXC chemokine receptor 4 (CXCR4), a G-protein coupled receptor, is expressed at low levels in the mature neutrophil. As they age, neutrophils alter their phenotype and upregulate CXCR4. This change supports homing to the bone marrow via the chemoattractant stromal-derived factor 1 (SDF-1 or CXCL12). Once back in the marrow, senescent neutrophils are phagocytosed by stromal macrophages.⁵ Senescent or apoptotic bloodstream neutrophils are also cleared by liver and spleen macrophages (reticuloendothelial system). Although little is known about the molecular mechanisms underlying neutrophil clearance in the liver and spleen, upregulation of the adhesion molecule P-selectin on Kupffer cells appears to be relevant. It remains a matter of speculation whether tissue neutrophils are cleared primarily via local macrophages.

Neutrophil Morphology and Content

Neutrophil nuclei tend to have more lobes than nuclei of other polymorphs, typically three to five (Figures 11-1 and 11-2). The multilobed nature of this nucleus reflects a

condensation of chromatin and suggests that neutrophils might be incapable of transcription. It is now appreciated, however, that neutrophils retain the capacity for constitutive and stimulated protein synthesis, albeit at a limited rate.

Neutrophil granules identifiable by classic histochemical staining comprise two classes (see Figure 11-1). Neutrophil *primary granules* form first and, by virtue of their staining tendencies (affinity for the basic dye azure A), are also referred to as *azurophilic granules*.⁶ These granules are oval or round and vary in size. They are similar, and functionally equivalent, to the lysosomes of other cells. In contrast, neutrophil *secondary granules* constitute a population unique to neutrophils, a fact reflected in the alternative nomenclature of *specific granules* often used to describe these

Figure 11-2 Resting neutrophils and eosinophils under light microscopy. A blood smear stained with hematoxylin and eosin showing neutrophils and eosinophils; the three-lobulated nucleus (polymorphonuclear) cells are characteristic of neutrophil morphology. Two eosinophils are distinguished by their bilobed nuclei and pink-stained granules (eosin stains basic structures). (Courtesy K.A. Zarembek, Laboratory of Host Defenses, National Institute of Allergy and Infectious Diseases, National Institutes of Health.)

structures. Characteristic of azurophilic granules is the presence of myeloperoxidase (MPO), an enzyme that catalyzes the formation of hypochlorous acid from chloride in the presence of superoxide anion (O_2^-). The presence of large amounts of this enzyme in azurophilic granules lends collections of neutrophils (pus) their typical greenish yellow color. Consistent with their role as lysosomes, azurophilic granules also contain a variety of proteases and other enzymes including elastase, lysozyme, acid phosphatase, and cathepsins and enzymes directed at nucleic acids and sugars. At the membrane level, however, they differ from true lysosomes because they lack lysosome-associated membrane proteins 1 and 2 (LAMP-1 and LAMP-2) and the mannose-6-phosphate receptor system.⁷ In contrast to azurophilic granules, specific granules possess an extensive array of membrane-associated proteins including cytochromes, signaling molecules, and receptors. Specific granules constitute a reservoir of proteins destined for topologically external surfaces of phagocytic vacuoles and the plasma membrane (Table 11-1).⁶ One particularly important family of proteinases found in neutrophil specific granules are the matrix metalloproteinases (MMPs) including neutrophil collagenase-2 (MMP-8), gelatinase-B (MMP-9), stromelysin (MMP-3), and leukolysin (MMP-25). They are stored as inactive proenzymes and undergo proteolytic activation after granule fusion and interaction with azurophilic granules, gaining the ability to alter integral components of bacterial membranes. Neutrophil MMP function is not limited to bacterial killing because MMPs are also important for extravasation and diapedesis.⁸

Further study has confirmed the existence of two additional classes of vesicles. Gelatinase granules are almost identical in size to specific granules and share some proteins in common with them. As their name implies, however, gelatinase granules are distinguished by their high concentrations of gelatinase, a latent enzyme with the capacity for tissue destruction.⁹ Secretory vesicles are smaller and lighter than the other classes and do not seem to contain proteolytic enzymes.¹⁰ Rather, secretory vesicles are noteworthy for an extensive complement of membrane-associated proteins including receptors otherwise identified with the plasma

membrane. These and other data suggest that the secretory vesicle is a reservoir of neutrophil plasma membrane and other membrane proteins.

Azurophilic and specific granules further contain antimicrobial proteins and peptides that are a cornerstone of innate immunity. A detailed description of the neutrophil's armamentarium against foreign invaders is beyond the scope of this chapter, but a few whose mechanisms of action have more recently been elucidated warrant mention. Elastase, mentioned previously, aids in the killing of gram-negative bacteria via degradation of bacterial outer membrane protein A.¹¹ Elastase-deficient mice are more susceptible to infection with gram-negative (but not gram-positive) organisms than wild-type mice. The defensins, normally located in azurophilic granules, are found in mg/mL concentrations in the phagocytic vacuole (see later) and render target cell membranes permeable. Bactericidal/permeability-inducing protein, also located in azurophilic granules, acts in concert with the defensins; it potently neutralizes endotoxin and is cytotoxic to gram-negative bacteria. Bactericidal/permeability-inducing protein also enhances the activity of secretory phospholipase A_2 , which has activity against gram-negative and gram-positive bacteria. Lactoferrin (found in specific granules) deprives microorganisms of iron and has antiviral and antibacterial effects. Other granule-associated proteins such as cysteine-rich secretory protein 3 (CRISP3) and ficolin 1 have recently been described, although their function is still unclear.

Neutrophil granule contents might play important roles beyond their direct antimicrobial effects; they also may amplify or dampen the innate and adaptive immune response. Lactoferrin released during phagocytosis may inhibit proliferation of mixed lymphocyte cultures by decreasing release of interleukin (IL)-2, TNF, and IL-1. Proteinase 3 has been found to augment release of active TNF and IL-1 in monocyte/neutrophil co-cultures by releasing the membrane-bound forms of these cytokines.¹² Gelatinase B has been shown to convert latent IL-1 into its active form¹³ and to potentiate IL-8 activity by truncating this chemoattractant and increasing its release, consequently amplifying neutrophilic influx.¹⁴ Neutrophil

Table 11-1 Neutrophil Granule Contents

	Secretory Vesicles	Gelatinase Granules	Specific Granules	Azurophilic Granules
Relative size	Smallest	Intermediate	Intermediate	Largest
Soluble components	Plasma proteins	Gelatinase Acetyltransferase	Gelatinase MMP-3 MMP-8 MMP-9 Lactoferrin β_2 -Microglobulin	Myeloperoxidase Glucuronidase Elastase Lysozyme Proteinase 3 α_1 -Antitrypsin Defensins Cathepsins BPI
Membrane-associated components	FMLP receptor CD11b/CD18 Cytochrome b_{558} Alkaline phosphatase Uroplasinogen activator CD10, CD13, CD16, CD45 CR1 Decay accelerating factor	FMLP receptor CD11b/CD18 Deacylating enzyme	FMLP receptor CD11b/CD18 Cytochrome b_{558} CD66, CD67 Fibronectin receptor TNF receptor	CD63, CD68

BPI, bactericidal/permeability-increasing protein; FMLP, formyl-methionyl-leucyl-phenylalanine; MMP, matrix metalloproteinase; TNF, tumor necrosis factor.

elastase also may play a proinflammatory role by virtue of its ability to cleave and disrupt phosphatidyl serine receptors on macrophages. Apoptotic cells undergo membrane alterations that lead to expression of phosphatidyl serine on their outer membrane surface, and interaction of phosphatidyl serine with its receptor leads to macrophage responses that downregulate inflammation through the generation of transforming growth factor (TGF)- β .¹⁵ By disrupting these interactions, the presence of neutrophil elastase may permit inflammation to continue.

Neutrophil Activation and Function

For bloodstream neutrophils to destroy foreign targets in the periphery, they first must sense the presence of such targets at a distance. They must then attach to the activated endothelium through multiple interactions involving adhesion molecules and their receptors (rolling and adhesion). After passing through the endothelium of postcapillary venules (diapedesis), neutrophils migrate to the source of the signal (chemotaxis). Finally, neutrophils must encounter a target, engulf it, and destroy it. Collectively, these processes are referred to as *neutrophil activation*. Because of the potential for tissue destruction, neutrophil activation must be carefully regulated. The internal responses through which a cell translates an encounter with a stimulus into a particular

phenotypic response are termed *signal transduction* (Figure 11-3).¹⁶

Stimuli and Receptors

Classic chemoattractants include lipid mediators (e.g., leukotriene B₄ [LTB₄], platelet-activating factor) and proteins/peptides (e.g., formylated peptides, the complement split product C5a, and IL-8). Chemoattractants *in vivo* are formed at sites of inflammation—either produced at the site by inflammatory cells such as LTB₄ or IL-8 or liberated from already synthesized proteins, as in the case of C5a. The ability of formylated peptides such as *N*-formyl-methionyl-leucyl-phenylalanine to stimulate neutrophils probably represents a particularly ancient arm of the innate immune response because prokaryotic, but not eukaryotic, cells synthesize proteins whose first amino acid is a formylated methionine. Chemoattractants also have the capacity to stimulate most other aspects of neutrophil activation. Their individual potencies for particular responses may differ,¹⁷ however, suggesting that they may serve overlapping but distinct functions in neutrophil activation. CXC chemokines are a recently described group of chemoattractants, characterized by the presence of two N-terminal cysteines (“C”) separated by any other amino acid (“X”) at the carboxy terminus. Many CXC chemokines appear essential

Figure 11-3 Signaling pathways in neutrophil activation. Engagement of Fc, growth factor, and chemoattractant receptors and adhesion molecules initiate signaling pathways that result in proinflammatory neutrophil responses including cytoskeletal and morphologic changes, activation of adhesion molecules and the superoxide generating system (NADPH oxidase), and regulation of transcription. Some of the well-established pathways participating in these responses are illustrated (see text for details).

for recruitment including IL-8 (CXCL8), KC (CXCL1), and MIP-2 (CXCL2).

Bloodstream activation of neutrophils depends on the presence of specific surface receptors. Most chemoattractant receptors belong to a class known as *seven-transmembrane-domain receptors*, “*serpentine seven*” receptors, or *G protein-coupled receptors* (GPCR); these receptors are composed of a single protein chain whose seven hydrophobic domains span the plasma membrane.¹⁸ Binding of a particular chemoattractant occurs in a pocket on the cytoplasmic face, close to or below the level of the plasma membrane. Receptors for soluble ligands other than chemoattractants have also been identified on neutrophils including receptors for growth factors, colony-stimulating factors, and cytokines, as described. These receptors fall into several families distinct from the serpentine sevens. Growth factor receptors are members of the protein tyrosine kinase receptor family, in which ligand interaction with two identical or related receptors brings them into proximity, causing their phosphorylation and activation. Recent systems biology studies have shown that receptors for a variety of inflammatory stimuli become highly expressed only in mature neutrophils.¹⁹ The most notable examples include CXC and CC chemokine receptors such as IL-8R- α and β ; CXCR-4 and CCR-1, 2, and 3; the cytokine receptors for TNF 1 and 2; interferon (IFN)- α and γ ; and interleukin receptors IL1R, IL4R, IL6R, IL10R, and IL17R. Some nonchemoattractant ligands do not directly activate neutrophils but may modulate their function. Pretreatment of neutrophils with either insulin or GM-CSF results in amplification of subsequent neutrophil responses to chemoattractants, a process referred to as *priming*.

G Proteins

Ligation of seven-transmembrane-domain receptors results in the interaction of cytoplasmic elements of the receptor with a class of effectors known as *heterotrimeric guanosine triphosphate (GTP)-binding proteins* (G proteins). G proteins are composed of α , β , and γ subunits, and individual G protein types are distinguished by their particular combination of subunits. In neutrophils, the predominant G proteins are of the G_i family. G protein γ subunits are modified by the addition of prenyl (polyisoprene) and carboxy-terminal methyl groups, which serve to anchor them to the plasma membrane. All G proteins share the capacity, localized to their α subunits, to bind GTP and subsequently to hydrolyze it to guanosine diphosphate (GDP). G proteins are active when GTP bound, but inactive in the GDP-bound form. Engagement of the appropriate seven-transmembrane-domain receptor results in the binding of GTP on the α subunit. As a consequence of GTP binding, heterotrimeric G proteins dissociate into α and β/γ components, each with specific effector functions.

A monomeric class of low-molecular-weight (20 to 25 kD) GTP-binding proteins (LMW-GBPs) has also been described. Because the first prototypic LMW-GBP to be described was the proto-oncogene Ras, these also are referred to as *Ras-related* or *Ras superfamily proteins*, or *small GTPases*. LMW-GBPs combine, in one molecule, the prenyl and methyl modifications of the G protein γ subunit with the GTP-binding capacity of the α subunit. At least four

families of LMW-GBP have been described: the Ras family, whose members play roles in activation as well as cell growth and division; the Rho family, which functions in cytoskeletal rearrangements; and the Rab and Arf families, which are crucial for vesicular and endomembrane trafficking.²⁰ All four classes of LMW-GBPs are represented in neutrophils.

Second Messengers

Second messengers are small, diffusible molecules that are generated in response to stimuli and transmit signals from membrane receptors to downstream effector proteins. In the classic model of neutrophil activation, engagement of receptors results in the activation of phospholipase C, which cleaves phosphatidylinositol triphosphate (PIP₃) into diacylglycerol (DAG) and inositol 1,4,5-triphosphate (IP₃). DAG and IP₃ mediate the influx of cytosolic calcium and the activation of protein kinase C (PKC). Other phospholipases present in the neutrophil include phospholipase A₂ (cPLA₂), which cleaves phosphatidylcholine or ethanolamine, or both, and is responsible for the generation of arachidonic acid (AA) and phospholipase D, which cleaves phosphatidylcholine into phosphatidic acid and choline.²¹ Although all the previously described second messengers have been implicated in neutrophil activation, other lipid mediators may have negative regulatory effects. Sphingosine and ceramide each inhibits neutrophil phagocytosis.

In addition to lipids, other organic and inorganic messenger molecules have been characterized. Intracellular concentrations of cyclic adenosine monophosphate (cAMP), a classic second messenger, increase rapidly in neutrophils exposed to stimuli and inhibitors. cAMP in these settings is likely to provide a negative regulatory (off) signal because direct exposure to cAMP inhibits neutrophil responses, probably through the activation of protein kinase A (PKA).¹⁷ In contrast, increases in cyclic guanosine monophosphate (cGMP) have a modest enhancing effect on some neutrophil responses. Nitric oxide (NO), an important molecule in the regulation of host defense, is also produced in neutrophils, albeit in low levels.²² Endogenously produced NO in neutrophils is likely to play an important role in signal transduction; several studies have documented the capacity of exogenously added NO to exert a variety of effects including inhibition of reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, actin polymerization, and chemotaxis (see later). Excessive NO production has been implicated in many rheumatic diseases.²³

Kinases and Kinase Cascades

There has been explosive growth in understanding of how kinases—proteins capable of enzymatically adding phosphate groups to target molecules—contribute to signaling in myeloid and nonmyeloid cells. Protein kinase C (PKC), actually a family of kinases, was among the first kinases implicated in neutrophil activation and is activated in response to chemoattractants. The ability of phorbol myristate acetate (PMA), a synthetic activator of PKC, to stimulate neutrophil responses including adhesion and O₂⁻ generation supports a role for PKC in neutrophil

activation.²⁴ In addition, inhibitors of PKC (including chelerythrine chloride and staurosporine) block stimulation of neutrophil functions.

The mitogen-activated protein kinases (MAP kinases) are a family of serine threonine kinases including the extracellular regulating kinase (ERK), p38, and c-Jun amino terminal kinase (JNK) families. In neutrophils, chemoattractants and other stimuli are capable of activating p38, JNK, and ERK, on time courses consistent with neutrophil activation. A role for ERK activation in signaling for both neutrophil O_2^- and in neutrophil adhesion and phagocytosis has been demonstrated.^{17,25} Phosphatidylinositol 3-kinase (PI3K) is a set of related enzymes that are found in abundance in neutrophils and primarily catalyze the phosphorylation, not of proteins, but of the 3-position of phosphatidylinositol phospholipids. One of the main bioactive products of PI3K is phosphatidylinositol triphosphate (PIP₃). Chemoattractants such as *N*-formyl-methionyl-leucyl-phenylalanine (FMLP) rapidly activate PI3K in neutrophils, where it seems to play a role in diverse neutrophil functions including O_2^- generation, adhesion, and degranulation.²⁶ PI3K also may regulate neutrophil survival and apoptosis.

Neutrophil Adhesion

One of the earliest, crucial aspects of the inflammatory response is the ability of bloodstream neutrophils to adhere to vascular endothelium preparatory to movement into the tissues (Figure 11-4). Stimulated neutrophils also possess the ability to adhere to each other, a process termed *homotypic aggregation*, which may bring in vivo bloodstream neutrophils into proximity with neutrophils already adherent to the vessel or concentrate them at a site of inflammation. Extensive investigation has provided significant insight into the mechanisms involved in neutrophil adhesion. Several

Figure 11-4 Neutrophil adhesion to the vascular endothelium. *Left, Rolling.* An unstimulated neutrophil adheres with low affinity to the unstimulated endothelium of a postcapillary venule, a process mediated by the interaction of selectins (on neutrophil and endothelium) with sialylated glycoproteins and resulting in the rolling of neutrophils along the vessel wall. *Center, Tight adhesion.* Exposure of the neutrophil to chemoattractants results in activation of integrins (CD11a/CD18, CD11b/CD18); exposure of endothelium to cytokines results in the expression of intercellular adhesion molecules. These molecules interact, resulting in tight adhesion. Concurrently, selectins may be shed from the cell surfaces. *Right, Diapedesis.* A neutrophil undergoes diapedesis, passing across the endothelium and making its way through the basement membrane. Bloodstream neutrophils have the capacity to adhere to and move out of the vasculature in response to tissue signals for inflammation. ICAM, intercellular adhesion molecule.

families of interacting adhesion molecules have been shown to exist on neutrophils and endothelial cells including the selectins, integrins, intercellular adhesion molecules (ICAMs), and sialylated glycoproteins.

The selectins consist of three related molecules (L-selectin on leukocytes, E-selectin on endothelial cells, and P-selectin on activated platelets and endothelial cells) sharing a common structure of two or more complement regulatory domains, an epidermal growth factor-like domain, and a lectin domain. Each binds to a sialylated glycoprotein on the surface of its interacting cell: E-selectin binds to the sialyl Lewis^x antigen on neutrophils, P-selectin binds P-selectin glycoprotein-1 on neutrophils, and L-selectin binds P-selectin glycoprotein-1 and GlyCAM-1 on the endothelium. Selectin expression is largely constitutive, but selectin/sialylated glycoprotein interactions are of low affinity and transient. The result of these interactions is that a pool of bloodstream neutrophils is, at any one time, loosely marginated to the vascular surface and moving along it slowly in a rolling, tumbleweed-like motion. Exposure of neutrophils and endothelium to appropriate stimuli (e.g., adrenergic discharge, corticosteroids) leads to shedding of selectins and neutrophil release (stress demargination), with apparent increases in the peripheral neutrophil count.

The integrins are a large family of heterodimeric molecules generated by various combinations of α and β chains. Similar to the selectins, they require divalent cations (Ca^{2+} or Mg^{2+} or both) to engage their ligands. Neutrophils express three β_2 -type integrins, each constructed from a distinct α subcomponent (CD11a, CD11b, or CD11c) and a common β_2 chain (CD18). Integrins use the ICAMs as their counterligands. CD11b/CD18 (also called *Mac-1* or *CR3*) binds to fibrinogen, factor X, heparin, and the complement component iC3b in addition to ICAM and is most strongly implicated in neutrophil/endothelial and neutrophil/neutrophil interactions. In contrast to the selectins, neutrophil CD11b/CD18 is constitutively expressed but inactive; stimulation of neutrophils by chemoattractants and other agents results in changes in the activation state of CD11b/CD18 and increases its affinity for ICAMs and other ligands.²⁷ Stimulation of endothelium with cytokines such as IL-1 results in increased expression of ICAM-1 and ICAM-2, providing a coordinate mechanism for the regulation of adhesion. In contrast to selectin-mediated adhesion, integrin/ICAM interactions are high-affinity and persistent. Stimulation of rolling neutrophils results in their tight adhesion to vessel walls and constitutes the first committed step in the movement of neutrophils into the tissues. Additionally, engagement of integrins by their counterligands sends signals into the cell ("outside in" signaling), regulating selective cell responses such as cytoskeletal reorganization, oxidant production, and degranulation. Outside-in signaling through CD11b/CD18 also coordinates with signaling through Fc receptor Fc γ RIII (see later) to mediate phagocytosis of particles opsonized by IgG and the complement component iC3b. Crosstalk between neutrophils and endothelial cells has also been shown to be a CD11b/CD18-dependent event: cross-linking of CD18 on neutrophils leads to increased permeability of endothelial cells, probably through the release of neutrophil proteases.²⁸

The function of CD11a/CD18 on neutrophils has been controversial, but accumulating data indicate that this

Figure 11-5 Neutrophil diapedesis through the vascular endothelium. A neutrophil passing between, or through, one or more endothelial cells is illustrated. The characteristic neutrophil multilobed nucleus and multiple granule types are visible. The leading edge of the neutrophil, passing through the endothelium, is relatively devoid of granule contents, suggesting that it represents the formation of a specialized structure for diapedesis including the formation of F-actin cytoskeleton.

molecule may be necessary for neutrophil adhesion and emigration.²⁹ The function of CD11c/CD18 is less clear, although it may play a role in neutrophil phagocytic activity.

Diapedesis and Chemotaxis

The mechanism by which neutrophils pass through the endothelial barrier is unclear. One report suggests a model in which neutrophils pass directly through pores generated within the endothelial cells themselves, but neutrophils alternatively may pass between endothelial cells by disruption of cell-cell junctions (Figure 11-5).³⁰ Diapedesis occurs via homotypic interactions between adhesion molecules found on neutrophils and endothelial cells known as *platelet-endothelial cell adhesion molecules* (PECAMs). These molecules are concentrated at endothelial cell junctions, and antibodies that block PECAM inhibit transmigration in vitro by limiting neutrophils to the apical surface of the endothelium. Transmigrating neutrophils undergo upregulation of $\alpha 6 \beta 1$, an integrin that mediates binding to laminin (a key component of the perivascular basement membrane). Antibodies to $\alpha 6 \beta 1$ generally block neutrophil transmigration but fail to do so in a PECAM knockout mouse, implicating $\alpha 6 \beta 1$ /PECAM as crucial to the passage of neutrophils out of the vasculature.³¹ CD47, otherwise known as *integrin-associated protein*, and CD99, expressed on neutrophils and endothelial junctions, have also been implicated in neutrophil passage through the endothelium.

When beyond the endothelium, most neutrophils pause for a time before traversing the basement membrane (basal lamina). Classic studies by Huber and Weiss³² suggest that neutrophils pass through the basement membrane via active disruption of its patency, without elucidation of known

proteases or oxygen radicals. The disruptions are rapidly repaired by an unknown mechanism, probably involving the endothelium.

Chemotaxis in the direction of a gradient is achieved by the extension of membrane ruffles (lamellipodia), followed by anchorage of the ruffles to the substrate and withdrawal of the trailing edge of the cell in the direction of movement. These changes are accomplished primarily through rearrangement of the actin cytoskeleton after engaging chemotactic factor gradient that signals through GPCRs and PI3K. Actin is a 41-kD protein that exists as a soluble, globular monomeric form (G-actin) and as an insoluble linear polymer (F-actin). F-actin may be assembled (extended) at one end (barbed end) and disassembled at the other, under the control of regulatory molecules. During chemotaxis, F-actin formation and extension is concentrated at the leading edge of the neutrophil, permitting extension of the cell membrane (see Figure 11-5). Chemoattractant receptors also concentrate at the leading edge, defining the cell's directional response to the gradient (headlight phenomenon). As the neutrophil moves along, receptors that were formerly at the leading edge are swept to the tail and internalized.

Phagocytosis and Degranulation

Neutrophil phagocytosis of an encountered bacterium or other particle requires direct contact. Neutrophils are generally poor at phagocytosing unmodified targets, particularly encapsulated bacteria (Figure 11-6). Two mechanisms

Figure 11-6 Neutrophil engulfing bacteria. Neutrophils can internalize and kill many microbes, each phagocytic event resulting in the formation of a phagosome into which reactive oxygen species and hydrolytic enzymes are secreted. A transmission electron micrograph at the precise moment in which a bacterium is being phagocytosed by a neutrophil. (Courtesy K.A. Zarembka, D.E. Greenberg, and K. Nagashima, Laboratory of Host Defenses, National Institute of Allergy and Infectious Diseases, National Institutes of Health.)

for triggering phagocytosis have been defined. First, phagocytosis can be activated by direct neutrophil recognition of pathogen-associated molecular patterns, or PAMPs, which are small molecule motifs found on or in bacteria or viruses (but not typically mammalian cells). PAMPs are recognized by Toll-like receptors (TLRs)³³ and other pattern recognition receptors (PRRs). Human neutrophils express all TLRs except for TLR3, and TLR activation stimulates human neutrophil phagocytosis by promoting structural and conformational changes.³⁴ Second, phagocytosis also depends on opsonization (from the Greek, “to prepare for the table”), the modification of a target via its decoration with immunoglobulin or complement components or both. Neutrophils express two families of receptors for the Fc portion of complexed or aggregated IgG: low-affinity FcγRIIa and high-affinity FcγRIIIb. During some infections, or after in vitro stimulation with interferon or G-CSF, neutrophils also express the high-affinity receptor FcγRI, which binds monomeric IgG.

FcγRIIa binds subclasses of IgG with varying efficiency depending on a polymorphism at amino acid position 131. Confusingly, the “low-responder” allotype (so named because of its weak interaction with mouse IgG₁) binds human IgG₂ efficiently, whereas the “high-responder” allotype (which binds mouse IgG₁ efficiently) does not. FcγRIIIb polymorphisms of neutrophil antigens NA1 and NA2 also determine binding to IgG subclasses. Individuals homozygous for the NA2 allele have a lower capacity to mediate phagocytosis than individuals homozygous for the NA1 allele. These differences have important implications for rheumatic diseases in which immune complexes play an important role (see later).

Phagocytosis is an active process that involves extension of the neutrophil membrane (filopodia and lamellipodia formation) and invagination of the neutrophil at the locus of the target. Engagement of FcγR and complement receptors results in the activation of diverse signaling pathways. Elegant studies by Caron and Hall indicate that FcγR and complement receptors play distinct roles in phagocytosis.³⁵ Whereas engagement of CR3 (CD11b/CD18) results in actin stress fiber formation and invagination, engagement of FcγRII results primarily in extension of membranes out from and around the target. Signaling by these receptors depends on the activation of distinct members of the Rho family of LMW-GDPs. These observations remain to be specifically confirmed for neutrophils, however. On activation, neutrophils degranulate, a term actually reflecting two distinct processes. Vesicles can fuse with the plasma membrane, spilling their contents into the extracellular space (see Figure 11-1), or they can fuse with the phagocytic vacuole to form a phagolysosome. The former type of degranulation is regulated differentially from the latter and favors mobilization of lighter granules in response to stimuli (secretory vesicles > gelatinase granules > specific granules > azurophilic granules). In the latter type of degranulation (phagolysosome formation), fusion of azurophilic granules with the phagocytic vacuole results in the delivery of proteolytic enzymes, myeloperoxidase, and antibacterial proteins to the site of the ingested bacterium. Fusion of specific granules with the phagocytic vacuole permits the delivery of collagenase and the appropriate localization of cytochrome *b*₅₅₈, a requisite for NADPH oxidase (see later).

Containment of potentially toxic substrates within the phagolysosome keeps host tissue damage and neutrophil autodestruction in check.³⁶ As discussed subsequently, however, in several of the rheumatic diseases, neutrophilic activation plays an important role in abetting inflammation and host tissue damage.

Reduced Nicotinamide Adenine Dinucleotide Phosphate Oxidase System

In addition to the collection of proteases and other antibacterial proteins contained in their granules, neutrophils have the capacity to kill bacteria through the generation of toxic oxygen metabolites such as nitric oxide (NO), superoxide anion (O₂[−]) and hydrogen peroxide (H₂O₂). This process, frequently referred to as the *respiratory burst*, is extremely potent and requires tight regulation to prevent neutrophil autodestruction. Studies in cell-free systems have established the so-called minimal system required for O₂[−] generation-NADPH oxidase.³⁷ The central component of NADPH oxidase is cytochrome *b*₅₅₈, which is localized to the membranes of specific granules and consists of two subunits: a 22-kD component (gp22^{phox}, for phagocyte oxidase) and a 91-kD component (gp91^{phox}). This cytochrome lacks independent activity, however. Three cytosolic proteins are also required: a 47-kD and a 67-kD component (p47^{phox} and p67^{phox}) and a LMW-GDP, p21^{rac}. On neutrophil stimulation, the p47^{phox} and p67^{phox} components translocate to the membranes to form an active complex with the cytochrome.³⁷ Although p21^{rac} also translocates in response to stimuli, the significance of its translocation is more controversial.³⁸ A fifth protein, p40^{phox}, also has been reported to be associated with p47/p67 in the cytosol. Evidence suggests that p40^{phox} may regulate the oxidase system in a positive and a negative manner (Figure 11-7)³⁹ and plays an important role in phagocytosis-induced superoxide production via a phox homology (PX) domain that binds to PIP₃. Moreover, autosomal recessive mutations in *NCF4*, the gene encoding p40^{phox}, have recently been associated with a form of chronic granulomatous disease⁴⁰ (see *Heritable Disorders of Neutrophil Function* later).

When assembled and activated, the NADPH oxidase transfers electrons from NADPH to generate O₂[−]:

A subsequent, spontaneous dismutase reaction rapidly produces hydrogen peroxide:

Although O₂[−] and H₂O₂ can kill organisms in vitro, they are short-lived and probably do not account for most of the bacterial killing capacity of the system under normal circumstances. (Many bacteria possess catalase, an enzyme that degrades H₂O₂.) Rather, the production of H₂O₂ within the same space into which the myeloperoxidase has been released permits the generation of large quantities of hypochlorous acid (chlorine bleach), a powerful oxidant with potent killing capacity. Hypochlorous acid may interact further with proteins to form chloramines, less potent but longer-lived oxidants. Neutrophil oxidant production plays

Figure 11-7 Assembly of the neutrophil NADPH oxidase system. *Top*, Basic components of the NADPH oxidase as they are distributed in a resting state. The cytochrome b_{558} , composed of the two subunits $gp91^{phox}$ and $p22^{phox}$, are membrane associated, whereas $p47^{phox}$, $p67^{phox}$, and the more recently identified $p40^{phox}$ exist as a complex in the cytoplasm. $p21^{rac}$ in an inactive, GDP-bound form also resides in the cytoplasm, in association with a chaperone (Rho-GDI) that sheaths its hydrophobic tail to permit solubility. *Bottom*, Activation of the neutrophil leads to translocation of the cytosolic components of the oxidase to the neutrophil membrane, where they form an active complex with the cytochrome, resulting in the generation of oxygen. The potentially damaging oxidase system is carefully regulated through the segregation and assembly of its component parts.

a key role in the body's defense against microorganisms. The current view that oxidant production, via the production of hypochlorous acid by myeloperoxidase, is the neutrophil's most powerful tool against microbes has been challenged, however. Mice lacking either NADPH oxidase or elastase and cathepsin G are susceptible to infection, implying that both arms of defense—oxidant production and protease-mediated microbial destruction—are equally crucial. Superoxide production in phagocytic vacuoles causes the pH to rise (secondary to the consumption of protons necessary to make H_2O_2), which causes an influx of K^+ . The resulting increase in ionicity liberates cationic proteases from the anionic proteoglycan matrix, freeing them to kill bacteria. In this new model, oxidants are not primarily destructive to microbes, but rather necessary to assist proteolytic damage.⁴¹ In support of this model is the fact that myeloperoxidase deficiency is common (1:2000) yet surprisingly benign.

Nonphagocytic Bacterial Killing

Novel distinctive mechanisms of bacterial killing by neutrophils can also augment host defense. Neutrophil extracellular traps, or NETs, are extracellular fibers composed of granule proteins and chromatin that bind and kill microorganisms (Figure 11-8).⁴² NETs are released on cellular activation. They entrap bacteria while simultaneously providing a scaffold to promote high local concentrations of antimicrobial components, thus killing microbes extracellularly. Because neutrophils die immediately after activating their NETs, this process has also been termed *beneficial suicide*.⁴³ Interestingly, these same NETs or related structures have recently been suggested to play roles in promoting clotting (including disseminated intravascular coagulation). In those cases, extruded neutrophil chromatin serves as a platform for the extracellular co-localization of neutrophil elastase and the antithrombotic tissue factor pathway inhibitor (TFPI). Inactivation of TFPI by elastase then permits clotting to proceed.⁴⁴

Neutrophil Production of Proinflammatory Mediators

Arachidonic Acid Metabolites

The capacity of stimulated neutrophils to liberate arachidonic acid from membranes has implications for the propagation of acute inflammation. Although arachidonic acid itself has chemoattractant and neutrophil-stimulatory properties,^{25,45,46} its metabolites are more crucial to regulation of inflammation. Best recognized among these are the leukotrienes. Neutrophils have the capacity to produce LTB_4 ,⁴⁵ a highly potent lipid mediator for the chemoattraction of other neutrophils. Intermediates of leukotriene production such as 5-hydroxyeicosatetraenoic acid also are produced by neutrophils and may have stimulatory properties.²⁵

Figure 11-8 Neutrophil extracellular traps (NETs). NETs are complex extracellular structures that are composed of chromatin, with specific proteins from the neutrophilic granules attached. NETs can trap gram-negative bacteria, gram-positive bacteria, and fungi. A scanning electron micrograph showing stimulated neutrophils forming NETs to trap *Shigella flexneri*. (Courtesy V. Brinkmann and A. Zychlinsky, Max Planck Institute for Infection.)

An alternative class of lipoxygenase products, the lipoxins, have been characterized.⁴⁵ Synthesis of lipoxins requires coordinated activity of neutrophil 5-lipoxygenase and a related enzyme (either 12-lipoxygenase or 15-lipoxygenase) in another cell type—either platelets or endothelial cells (Figure 11-9).⁴⁷ In contrast to leukotrienes, lipoxins inhibit neutrophil function and are anti-inflammatory,⁴⁸ suggesting that the assembly of a mixed population of inflammatory cells may trigger the synthesis of anti-inflammatory molecules (resolvins), contributing to the subsequent resolution of inflammation (see section on [Resolution of Neutrophil Infiltration and Apoptosis](#)). The cyclooxygenase (COX) (endoperoxide synthase) pathway is the other major pathway of arachidonic acid metabolism. Arachidonic acid metabolized by COX is converted into prostaglandin H,⁴⁹ which undergoes further cell type-specific conversion to a variety of other prostaglandins. The prostaglandins of most relevance to inflammation are those of the E series, particularly prostaglandin E₂. Prostaglandins of the E series have numerous proinflammatory effects including increased vasodilation, vascular permeability, and pain. However, the direct effects of prostaglandin E on neutrophils seem to be inhibitory, probably through elevations of intracellular cAMP.⁵⁰ Although resting neutrophils exhibit little COX activity, persistent neutrophil activation results in upregulation of COX-2, suggesting that neutrophils may contribute prostaglandin E₂ to both the proinflammatory brew and the downregulation of their own activity.

Figure 11-9 Generation of the anti-inflammatory lipoxins A₄ and B₄ depends on the interaction between two different classes of inflammatory cells. *Top*, Lipoxin generation by neutrophils and platelets. Arachidonic acid (AA) generated by activated neutrophils is converted by neutrophil 5-lipoxygenase (5-LO) into leukotriene A₄ (LTA₄). LTA₄ may be converted by 12-LO in nearby platelets into lipoxin A₄ (LXA₄) and lipoxin B₄ (LXB₄). *Bottom*, Lipoxin generation by epithelial cells and neutrophils. AA generated by epithelial cells may be converted by 15-LO into 15-hydroxyeicosatetraenoic acid (15-HETE). In the setting of inflammation, 5-LO from adjacent neutrophils subsequently may convert 15-HETE into LXA₄ and LXB₄.

Cytokine Production

Although the relative amount of cytokine production by neutrophils is small, the large numbers of neutrophils present in infected or inflammatory sites suggest that overall neutrophil cytokine production may play a role in recruiting additional neutrophils to the target area. Among the cytokines produced by neutrophils are IL-8, IL-12, MIP-1 α and β (CCL3 and CCL4), growth-related oncogene- α (GRO- α), oncostatin M, MCP-1, and TGF- β . Neutrophils do not produce IL-1, TNF, and IL-6, the classical products of macrophages and synovial cells.⁵¹ The transcriptional program of terminally differentiated neutrophils requires a selective combination of stimulants for the production of chemokines. In the presence of lipopolysaccharide, TNF drives production of IL-8, GRO- α , and MIP-1, whereas IFN- γ is necessary to generate CXCL9 and 10.⁵² Other neutrophil-derived molecules have been identified as bridging factors between innate and adaptive immunity. Following either G-CSF or IL-8 stimulation, activated neutrophils release both B-lymphocyte stimulator (BLYS) and TNF-related apoptosis-inducing ligand (TRAIL).^{53,54} While BLYS stimulates B cell proliferation (through the TNF receptors BAFF-R, TACI, and BCMA), TRAIL induces antitumor T cell effects and apoptosis.

More recently, multiple lines of investigation have suggested that neutrophils may also be a source for IL-17, a potent proinflammatory cytokine, which can amplify the neutrophil migration and recruitment.⁵⁵ It is still unknown, however, whether neutrophils express IL-23R (required for most IL-17 producing cells) or can induce transcriptional factors that regulate IL-17 production (such as ROR γ or STAT3).⁵⁶

TGF- β is a powerful neutrophil chemoattractant,⁵⁷ and its recruitment of neutrophils into an inflammatory space may lead to additional neutrophil cytokine production, including further production of TGF- β .⁵⁷ TGF- β also has potent anti-inflammatory effects,¹⁵ however, suggesting that neutrophils may also participate in the resolution of inflammation. Activated neutrophils also produce an antagonist to IL-1, the IL-1 receptor antagonist.⁵⁸ The efficacy of recombinant IL-1 receptor antagonist (anakinra) in the treatment of rheumatoid arthritis and in autoinflammatory diseases such as Still's disease emphasizes its clinical importance in downregulating synovial inflammation.

Resolution of Neutrophil Infiltration and Apoptosis

Inflammatory responses must eventually be resolved to avoid excessive tissue damage and initiate the healing process. Resolution of inflammation is an active and carefully regulated process. Proresolution signals include lipid mediators such as lipoxins and resolvins, annexin A1 and chemerin-derived peptides, and certain chemokines and cytokines.

Two types of resolvins are described, depending on the lipid from which they are derived. E-resolvin is a product of eicosapentaenoic acid (EPA), whereas D-resolvin derives from docosahexaenoic acid (DHA). Resolvin E1, for instance, acts on monocytes, macrophages and dendritic cells (DCs), attenuating TNF-mediated nuclear factor

kappa B (NF κ B) activation, leading to an active anti-inflammatory pathway.⁵⁹ At the same time, Resolvin E1 selectively interacts with the selective LTB₄ receptor BLT1 on neutrophils to regulate inflammation,⁶⁰ suggesting a tightly coordinated feedback loop. Resolvin D is also a potent inhibitor of neutrophil diapedesis and migration, particularly in the brain, where DHA is highly abundant.⁶¹ The most recently described resolvin, macrophage mediator in resolving inflammation 1 (maresin 1), has properties similar to the D-resolvins.⁶² Aspirin has been shown to stimulate the generation of biologically active epilipoxins, suggesting a previously unappreciated mechanism for its anti-inflammatory action.⁶³ Even some prostaglandins such as 15d-PGJ₂ also have anti-inflammatory properties.⁶⁴

Following neutrophil activation, annexin A1 (lipocortin) is released in response to chemoattractants, downregulating transmigration and promoting neutrophil apoptosis and clearance.⁶⁵ Similar activities have recently been attributed to chemerin-derived peptides.⁶⁶ Apoptotic neutrophils at sites of inflammation are taken up by resident macrophages, promoting lipoxin A4 production,⁶⁷ which inhibits polymorphonuclear neutrophil migration and promotes cell arrest while decreasing neutrophil activity and cytokine production. An MMP-mediated mechanism of inflammatory resolution has also been identified. Macrophage-derived MMPs such as MMP-1, MMP-3, and MMP-12 cleave several CXC-chemokines, provoking the loss of their neutrophil-recruiting activity⁶⁸ and dampening the influx of cells.

Apoptotic neutrophils themselves can prevent further chemotaxis and migration through negative feedback loops. Dead neutrophils inhibit migration of granulocytes via release of lactoferrin⁶⁹ and annexin A1. Apoptotic neutrophils can also suppress granulopoiesis, by inhibiting the proinflammatory consequences of IL-17/IL-23 axis activation. In this model, macrophage and DCs produce IL-23 at the site of insult, which in turn promotes IL-17 production by T cells (Th17, $\gamma\delta$ T cells, and natural killer [NK] T cells). IL-17 is a promoter of G-CSF production and a powerful neutrophil chemoattractant. Recruited neutrophils undergo apoptosis and are phagocytosed by macrophages, resulting in a decrease of IL-23. This is followed by a reduction in IL-17 and G-CSF production, which downregulates granulopoiesis.⁷⁰ The role of SDF-1/CXCR4 signaling system in neutrophil homeostasis has been described earlier (see **Neutrophil Myelopoiesis and Clearance**).

An intriguing mechanism through which neutrophils might downregulate the action of protein inflammatory mediators has been defined. Apoptotic neutrophils (present during the resolving phase of inflammation) show increased expression of the chemokine receptor CCR5 on their surface (mediated by D and E resolvins), and this receptor can scavenge, and reduce the soluble concentration of, chemokines such as CCL3 and CCL5. These data emphasize again that neutrophils are not only inflammatory cells but may also play a direct role in the subsequent resolution of inflammation.⁷¹

Heritable Disorders of Neutrophil Function

A wide variety of acquired conditions result in neutrophil dysfunction, depletion, or both including malignancies

(myeloid leukemias), metabolic abnormalities (diabetes), and drugs (corticosteroids, chemotherapy). In addition, many rare, congenital disorders of neutrophils have been identified (Table 11-2). In general, patients with impaired neutrophil function are prone to infection by bacteria (predominantly *Staphylococcus aureus*, *Pseudomonas* species, *Burkholderia*) and fungi (*Aspergillus*, *Candida*), but not viruses and parasites. The major sites of infection include skin, mucous membranes, and lungs, but any site may be affected and spreading abscesses are common. Most of these diseases are potentially life threatening in the absence of available effective therapy.

Diseases of Diminished Neutrophil Number

Severe congenital neutropenia (SCN, Kostmann's syndrome) results from marrow arrest of bone marrow myelopoiesis and leads to neutrophil counts persistently less than 0.5×10^9 cells/L. Monogenic autosomal dominant, autosomal recessive, and sporadic subtypes were initially identified.⁷² However, some SCN patients have recently been identified as carriers of mutations in multiple genes.⁷³ Patients are prone from early infancy to severe bacterial infections including omphalitis, pneumonia, otitis, gingivitis, and perirectal infections. Because acute inflammation is lacking, infections tend to spread extensively before coming to attention. Mortality has been high. Therapy consists of antibiotics and long-term therapy with recombinant human G-CSF, which may help maintain normal or near-normal neutrophil counts. SCN patients are also at risk for acute myeloid leukemia (AML) and myelodysplastic syndrome,⁷⁴ particularly in patients who do not respond well to G-CSF therapy. A milder form of neutropenia (benign congenital neutropenia) with higher neutrophil counts and fewer infections has also been observed. Another variant is cyclic neutropenia, which causes transient, recurrent neutropenia on a 21-day cycle. Studies suggest that defects in neutrophil elastase affect neutrophil survival in the marrow and may be responsible for severe congenital and cyclic neutropenia.⁷⁵ At least 52 different mutations in the *ELANE* gene, encoding for neutrophil elastase, have been described as the cause in around half of the patients.⁷⁶ Mutations in HAX-1 and Glucose-6-phosphatase catalytic subunit 3 (G6PC3) genes account for a smaller proportion of SCN. Other, less frequent deficiencies include the X-linked neutropenia—caused by constitutively active mutations of the WASP gene—and defects in several myeloid transcription factors.

Leukocyte Adhesion Deficiencies

Leukocyte adhesion disorders arise from defects in cell adhesion to extracellular matrix and vascular endothelium. Three distinct entities have been described in humans. Leukocyte adhesion deficiency type 1 (LAD1) results from an autosomal recessive defect in ITGB2, encoding for the CD18 chain of β 2 integrins. Consequently, neutrophil β 2 integrins fail to form,⁷⁷ and bloodstream neutrophils are unable to adhere firmly to vascular endothelium and to transmigrate to sites of infection. Phagocytosis is also impaired. The clinical picture is similar to that of the neutropenias, with recurrent life-threatening infections. Peripheral neutrophil counts are typically elevated, however,

Table 11-2 Heritable Disorders of Neutrophil Function

Disorder	Defect	Inheritance	Presentation	Therapy	Typical Prognosis
Neutropenia					
Severe congenital neutropenia (Kostmann's syndrome)	Maturation arrest ($<0.5 \times 10^9$ PMN/L)	AR (HAX1 mutations)	Bacterial infections (omphalitis, abscesses, gingivitis, UTIs)	RhG-CSF	Improved with treatment
Benign congenital neutropenia	Multiple etiologies ($0.2\text{--}2 \times 10^9$ PMN/L)	Variable	Mild infections	None	Good
Cyclic neutropenia	Stem cell defect, elastase gene deficiency (nadir every 21 days)	AD (ELA2 mutations)	Infection during nadirs	RhG-CSF	Improved with treatment
Adhesion Deficiency					
Leukocyte adhesion deficiency type 1	Absent or abnormal CD18; deficiency in $\beta 2$ -integrin chain of leukocyte adhesion molecules	AR	Leukocytosis; recurrent infections (skin mucous, membranes, gastrointestinal tract)	Marrow transplant	Fair-poor
Leukocyte adhesion deficiency type 2	Absent sialyl-Lewis ^x	AR	Neutrophilia; infection; retardation, short stature		Poor
Leukocyte adhesion deficiency type 3	Impaired activation of Rap1 GTPase	AR	Leukocytosis; recurrent infections; bleeding tendency		Poor
Chemotaxis Deficiency					
Hyper-IgE syndrome	Chemotaxis defect	AD	Eczema; recurrent infections; elevated serum IgE levels	Skin care; antibiotics	Good
Granule Disorders					
Chédiak-Higashi syndrome	Defective lysosomal trafficking regulator gene	AR	Albinism; infection	Marrow transplant; antibiotics	Poor
Specific granule deficiency	Abnormal/reduced specific and azurophilic granules (lactoferrin deficiency)	AR?	Infection of skin, mucous membranes, lungs		Fair-good
Myeloperoxidase deficiency	Myeloperoxidase absent	Variable (mostly AR)	None	Transfusion of HLA identical leukocytes if severe	Excellent
p14 deficiency	Defective endosomal adapter protein gene	Recessive	Albinism; infection; short stature	None known to date	?
Oxidase Defects					
Chronic granulomatous disease (multiple types)	gp91 ^{phox} absent p22 ^{phox} absent p47 ^{phox} absent p67 ^{phox} absent p40 ^{phox} absent	X-linked 50% AR 5% AR 35% AR 5% AR 5%	Early childhood infections, especially skin and mucous membranes, abscesses	Interferon- γ	Improved with treatment

AR, autosomal, recessive; PMN, polymorphonuclear neutrophil; RhG-CSF, recombinant human granulocyte colony-stimulating factor; UTIs, urinary tract infections.

reflecting the intravascular accumulation of cells in the face of their inability to exit the vessels. Complete LAD1 manifests in infancy and is characterized by omphalitis, recurrent life-threatening bacterial and fungal infections, gingivitis, and delayed wound healing. Absence of pus at sites of infection is a hallmark of LAD1. Bone marrow transplantation is the only curative therapy. LAD2 results from an autosomal recessive defect in the glycosylation of sialyl Lewis^x

(SLex or CD15s), the neutrophil counterligand for endothelial selectins. Patients with LAD2 have neutrophils that are unable to roll along the endothelium and have symptoms similar to LAD1 but may also have mental retardation, short stature, distinctive facies, and the Bombay (hh) blood type.⁷⁸ A third variant, LAD3, has been described in which leukocytes have normal populations of surface integrins but lack the ability to signal these molecules into an active

state.⁷⁹ Because integrin activation in this condition is also deficient in platelets, patients with LAD3 are at increased risk for infection and bleeding.

Neutrophil Granule Defects

The best-known defect in neutrophil granule formation is Chédiak-Higashi syndrome. Chédiak-Higashi syndrome is an autosomal recessive disorder in which granule subtypes—in neutrophils, but also in lymphocytes, melanocytes, Schwann cells, and others—undergo disordered fusion, resulting in giant, dysfunctional granules. The cause seems to relate to a defect in the gene for lysosomal transport protein (Lyst or CHS1).⁸⁰ Patients with Chédiak-Higashi syndrome present with partial oculocutaneous albinism, neutropenia, frequent infection, mild bleeding diathesis, and neurologic abnormalities. Approximately 85% of patients who survive childhood enter a so-called accelerated phase, a lymphoma-like infiltration of lymphocytes and histiocytes throughout the body, which is generally fatal. Other diseases of neutrophil granules have less ominous prognoses. A novel immunodeficiency syndrome relating to lack of the endosomal adapter protein p14 (encoded by the *ROBLD3* gene) has been described. Patients with this syndrome have congenital neutropenia with structurally abnormal neutrophil primary granules and abnormalities of B cells, cytotoxic T cells, and melanocytes. In addition to immunodeficiency, clinical findings include short stature and partial albinism.⁸¹

Oxidase Deficiencies—Chronic Granulomatous Disease

Chronic granulomatous disease (CGD) resembles other diseases of neutrophil dysfunction in that it results in severe, recurrent infections of the skin and mucous membranes. Osteomyelitis and intra-abdominal abscesses are common. In contrast to the other diseases, infection in patients with CGD generally results in a delayed but quantitatively normal neutrophil response. Because of incapacity to kill organisms, however, the accumulation of neutrophils at a site of infection generally results in granuloma formation, rather than clearance of the target. Cutaneous infections tend to show persistent drainage and scarring. The presence of even partially responsive neutrophils results in a lower frequency of sepsis in these patients relative to patients with absolute neutropenia. CGD is typically a disease of early childhood, although some milder cases may be recognized later in life.

CGD is actually a group of diseases. In each, a genetic defect in a different component of NADPH oxidase results in failure of neutrophils (and other phagocytes) to generate O_2^- , impairing both intracellular killing and the ability of neutrophils to generate NETS.^{42,43} X-linked CGD affecting gp91^{phox} (CYBB gene) is the most common form and accounts for about 70% of cases, whereas the autosomal recessive forms are responsible for the rest.⁸² Treatment for chronic granulomatous disease consists of aggressive antibiotic prophylaxis and therapy, along with long-term therapy with recombinant human interferon- γ (IFN- γ) to improve neutrophil function. Clinical trials of gene therapy of X-linked CGD have yielded encouraging results.⁸³

Defects of TLR Signaling

Defects in human TLR signaling including IRAK-4 and MyD88 deficiencies lead to impaired neutrophil function and increased susceptibility to bacterial infections.^{84,85}

Neutrophil Relevance to Rheumatic Disease

Neutrophil-Mediated Tissue Destruction

Despite sophisticated regulatory mechanisms, tissue destruction by neutrophils is common. Several mechanisms may permit the release of neutrophil proteases and oxygen radicals into the extracellular milieu. First, necrosis or destruction of neutrophils, or both, may liberate cellular contents indiscriminately. Second, studies have revealed that degranulation and O_2^- generation may begin before complete closure of the phagocytic vacuole, releasing products either into the external environment (regurgitation during feeding) or against a target surface. Neutrophils may destroy host tissues that they have been misdirected to attack. Although serum and joint fluid contain antiproteases and antioxidants, the “protected space” between a neutrophil and a surface (e.g., cartilage) may exclude these factors. Release of hypochlorous acid, myeloperoxidase, and proteinases into the extracellular milieu may inactivate the protective compounds and act as an “antiprotease shield.”³²

Neutrophil Fc Receptor Polymorphisms

Given that polymorphisms of Fc γ R determine phagocytic capacity of IgG isotypes, it is not surprising that they determine susceptibility to diseases in which autoantibodies play a key role. Phagocytes from individuals with one Fc γ RIIa polymorphism (H131) allele are able to bind and phagocytose IgG₂; phagocytes from individuals with a different polymorphism (R131) cannot. In white European and African-American populations, patients with lupus nephritis have a higher frequency of the Fc γ RIIa-R131 allele than control groups; their relative inability to clear immune complexes may make them more susceptible to renal disease.⁸⁶ The significance of different Fc receptor polymorphisms may vary among rheumatologic diseases. Tse and colleagues found no association between Fc γ RIIa polymorphisms and likelihood of developing antineutrophil cytoplasmic antibody (ANCA)-associated vasculitides, but they found an overrepresentation of homozygosity for the Fc γ RIIb NA1 allele among patients with antimyeloperoxidase antibodies. Few studies have been published on Fc polymorphisms and susceptibility or severity of rheumatoid arthritis. More recent studies found no association among Fc γ RIIa, IIb, or IIIb haplotypes and rheumatoid arthritis susceptibility but did find a correlation between patients with extra-articular disease and the homozygous R/R 131 genotype. In contrast, Fc γ RIIIa receptor expression is increased in rheumatoid arthritis.⁸⁷

Gout

Gout may be the quintessential neutrophilic rheumatic disease. Although the initiation of an acute gouty attack involves the phagocytosis of urate crystals by synovial

macrophages and the generation of cytokines such as IL-1 and IL-8, the hallmark of acute gout is the presence of enormous numbers of neutrophils (sometimes $> 100,000/\text{mm}^3$) in the affected joint space. Urate crystals in the joint are capable of nonspecifically binding immunoglobulin and fixing complement by the classic and alternative pathways. C5a liberated from the complement fixation process attracts neutrophils to the joint space, where they phagocytose opsonized crystals via receptor-dependent mechanisms, resulting in further activation of the neutrophil and production of LTB₄, IL-8, and other mediators. Naked urate crystals can also directly activate neutrophils. Activation of neutrophils results in the ingress of additional neutrophils. Neutrophils in the gouty joint may damage joint structures through discharge of contents directly into the joint fluid during crystal phagocytosis or directly against cartilage during attempted phagocytosis of urate crystals embedded in or adherent to cartilage. In addition, interaction of phagocytosed urate crystals with lysosomal membranes results in the dissolution of the latter, spilling lysosomal proteases into the cytoplasm and, eventually, into the extracellular space.⁸⁸

Rheumatoid Arthritis

Rheumatoid arthritis may be conceptualized as a two-compartment inflammatory disease: In the synovium, lymphocytes, fibroblasts, and macrophages predominate, but the joint space contains a substantial percentage of neutrophils. Although the numbers of neutrophils in the rheumatoid joint tend to be less than those seen in gout, they are still quite large, with 10 billion cells per day cycling through a 30-mL effusion. The classic model suggests that rheumatoid factor-based immune complexes, produced in the pannus and present in the joint space in high concentrations, can fix complement and draw neutrophils into the joint space in high numbers. Once there, *in vitro* studies have documented the ability of neutrophils to bind to cartilage surfaces embedded with immune complexes and to damage them via incomplete phagocytosis. No adequate *in situ* demonstration of direct neutrophil attack on cartilage has been offered yet, however. The fact that seronegative arthritides such as psoriatic arthritis lack rheumatoid factor but nonetheless share with rheumatoid arthritis the presence of synovial hyperplasia and a large neutrophilic infiltrate in the joint space suggests that immune complex formation may be important, but not absolutely required, for neutrophil influx. The ability of rheumatoid synovial monocytic leukocytes to secrete IL-1 and IL-8 and other cytokines indicates that pannus itself may play an important role in the attraction of neutrophils out of the bloodstream and into the joint. Although few in number, neutrophils within the pannus have been documented to concentrate at the pannus/cartilage border, suggesting a possible role in pannus-driven marginal erosion.⁶³

In addition to promoting joint destruction, neutrophils in the rheumatoid joint may contribute to the propagation of pannus and of rheumatoid inflammation. As noted earlier, neutrophils themselves can produce proinflammatory cytokines; expression of several such cytokines including oncostatin M, MIP-1 α , and IL-8 is increased in rheumatoid neutrophils, especially from rheumatoid arthritis synovial

fluid.⁸⁹ Injection of lysates of neutrophil granules into joints in animal models produces a synovitis indistinguishable histologically from rheumatoid synovitis, an effect that can be reproduced by injection with purified active or inactive myeloperoxidase.⁹⁰ Neutrophil proteins also may regulate synovial proliferation through effects on other resident or immigrant cell populations. Neutrophil proteinase 3 may enhance the proinflammatory effects of monocytes, by cleaving and releasing active IL-1 and TNF from the surface of the latter. Neutrophil defensins enhance phagocytosis by macrophages and stimulate the activation and degranulation of mast cells, an interesting observation in light of a report that mice deficient in mast cells are resistant to the development of erosive arthritis.⁹¹ Neutrophil proteases also enhance the adherence of rheumatoid synovial fibroblasts to articular cartilage, and neutrophils may regulate synovial vascularization through the production of vascular endothelial growth factor, leading to endothelial proliferation.

Blood and synovial neutrophils from early rheumatoid arthritis patients also show significantly lower levels of apoptosis. This effect might be related to high levels of antiapoptotic cytokines such as IL-2, IL-4, IL-15, GM-CSF, and G-CSF found in joints of early RA patients.⁹² Lactoferrin is present at significant levels in established RA synovium and may delay spontaneous apoptosis of peripheral and synovial neutrophils.⁹³

Recently, studies by Lee and others have demonstrated that neutrophils are necessary for the propagation of rheumatic disease in mouse models of rheumatoid arthritis. These studies have implicated the ability of neutrophils to produce LTB₄, as well as the presence of FC γ RIIA and C5a receptors on the neutrophil surface as necessary for arthritis development.^{94,95} Intriguingly, several studies have raised the possibility that, under certain conditions of stimulation, neutrophils can serve as antigen-presenting cells. Neutrophils in rheumatoid arthritis synovial fluid synthesize and express large amounts of class II major histocompatibility complex. The importance of neutrophils to the rheumatoid process may be underscored by rheumatoid arthritis animal models in which mice deficient in neutrophils are resistant to the arthritic process.

Vasculitis

Neutrophils may be identified, to a greater or lesser degree, in the lesions of virtually all kinds of vasculitis. The mechanisms of neutrophil accumulation may vary, however, with different mechanisms predominating in different conditions. The early observation that infusions of allospecies serum produced acute inflammation in skin and joints (serum sickness), together with the appreciation that subcutaneous rechallenge with previously administered antigen leads to intense local inflammation (Arthus reaction), led to the development of a model in which immune complex deposition in the blood vessels results in complement activation and an influx of neutrophils to the affected site. Because immune complex formation is a hallmark of many primary rheumatic vasculitides (e.g., essential mixed cryoglobulinemia, hypersensitivity vasculitis, Henoch-Schönlein purpura), it is likely that immune complex deposition is crucial to the genesis of these diseases. In several of these vasculitides, neutrophil disruption and

fragmentation—*clasis*—is a prominent pathologic finding, leading to their designation under the rubric *leukocytoclastic vasculitis*. In some rheumatic diseases in which vasculitis is a secondary phenomenon, such as rheumatoid arthritis and systemic lupus erythematosus, the role of immune complex deposition is also implicit. It has been suggested that patients with lupus experience transient accumulations of neutrophils (leukoaggregation) in small vessels of the lungs and other tissues, as a result of complement activation within these vessels or in the soluble phase.⁹⁶

Induction of adhesion molecules on endothelial cells or neutrophils themselves or both is an alternative mechanism through which neutrophil accumulation in vessels may be propagated. The Shwartzman phenomenon, in which reinjection of cellular material leads to vascular inflammation via a cytokine-dependent, immune complex-independent mechanism, is a model for this avenue to vasculitis. Adhesion molecule upregulation may be particularly relevant to vasculitides in which immune complex formation is not a hallmark such as giant cell (temporal) arteritis. Detailed analyses of the inflammatory cells involved in giant cell arteritis indicate the presence of T cells producing IL-1 β and IL-6 that may act on vascular endothelium.⁹⁷ It is likely that many rheumatic diseases employ immune complex-dependent and immune complex-independent mechanisms in the pathogenesis of neutrophil ingress into vascular structures. In addition to the role of immune complexes, Belmont and colleagues⁹⁸ have shown the induction of adhesion molecules in patients with systemic lupus erythematosus.

Several vasculitides are noteworthy for the presence, in the serum of affected patients, of antibodies directed at cytoplasmic components of neutrophils (ANCA). ANCA-positive vasculitides are discussed in detail in Chapter 89.

Neutrophilic Dermatoses and Familial Mediterranean Fever

Sweet's syndrome, named after the physician who first described it in 1964, is characterized by fever, neutrophilia, and painful erythematous papules, nodules, and plaques. It can be subdivided into five groups: idiopathic, parainflammatory (associated with inflammatory bowel disease or infection), paraneoplastic (most commonly in the setting of leukemia), pregnancy related, and drug associated (usually after treatment with G-CSF). Most important clinically, it is a diagnosis of exclusion. Sweet's syndrome frequently appears after an upper respiratory tract infection and has a propensity to involve the face, neck, and upper extremities. When found on the legs, Sweet's syndrome lesions can be confused with erythema nodosum. Histopathology is characterized by dense neutrophilic infiltrate in the superficial dermis and edema of the dermal papillae and papillary dermis. Leukocytoclasia may suggest leukocytoclastic vasculitis, although vascular damage is absent. It is typically accompanied by peripheral neutrophilia. Treatment with systemic corticosteroids usually induces a dramatic resolution of the lesions and the systemic symptoms. Although the etiology of the disease is unclear, many authors believe that Sweet's syndrome may represent a form of hypersensitivity reaction to microbial or tumor antigens. Antibiotics do not influence the course of the disease in most patients.

Pyoderma gangrenosum is characterized by painful ulcerating cutaneous lesions over the lower extremities, usually in patients with an underlying inflammatory illness. Inflammatory bowel disease, rheumatoid arthritis, and seronegative arthritis are the most common associations, although an association with malignancy has also been reported. Fifteen percent of patients have a benign monoclonal gammopathy, usually IgA. Similar to Sweet's syndrome, pyoderma gangrenosum is a diagnosis of exclusion, is characterized on biopsy specimen by neutrophilic infiltrate, and usually remits with systemic corticosteroids, although topical and intralesional injections of corticosteroids may be beneficial as well. Other rare neutrophilic dermatoses include rheumatoid neutrophilic dermatitis, described as symmetric erythematous nodules on extensor surfaces of joints; bowel-associated dermatosis-arthritis syndrome occurring after bowel bypass surgery for obesity; and neutrophilic eccrine hidradenitis, sometimes linked to acute myelogenous leukemia.

In familial Mediterranean fever (discussed in detail in Chapter 97), patients experience episodic inflammatory exacerbations, characterized by large influxes of neutrophils. A defect in an anti-inflammatory protein, pyrin, seems to permit the inappropriate development of inflammation. Pyrin has been shown to be expressed exclusively in myeloid cells including neutrophils and eosinophils.

Effects of Antirheumatic Agents on Neutrophil Functions

Many antirheumatic therapies currently in use have been documented to act at least partly at the level of the neutrophil. Nonsteroidal anti-inflammatory drugs (NSAIDs) are the most frequently used class of antirheumatic agents. By virtue of their ability to inhibit COX activity and prostaglandin production, moderate doses of NSAIDs have diverse effects on inflammation including inhibition of vascular permeability and modulation of pain. At higher, clinically anti-inflammatory concentrations, NSAIDs inhibit chemoattractant-stimulated neutrophil CD11b/CD18-dependent adhesion and degranulation and NADPH oxidase activity.^{99,100} It is unlikely, however, that these effects are due solely to COX inhibition because (1) as noted earlier, neutrophils exhibit little COX activity under normal circumstances, and (2) concentrations of NSAIDs required to inhibit neutrophil function exceed the concentrations required to inhibit COX. High-dose NSAIDs seem to have other, pleiotropic effects on neutrophil signaling. Our laboratory has shown the capacity of aspirin and the poor COX inhibitor sodium salicylate to inhibit Erk activation in a manner consistent with inhibition of adhesion, suggesting that salicylates may have unique effects on inflammation.¹⁰¹

Similar to nonsteroidals, glucocorticoids exert potent effects on neutrophils including inhibition of neutrophil phagocytic activity and adhesive function. The ability of steroids to increase peripheral blood neutrophil populations acutely—an effect known as *demargination*—is attributable to both a release of neutrophils from the bone marrow and the release (demargination) of neutrophils adherent to vessel walls. In addition, glucocorticoids inhibit phospholipase A₂ and leukotriene and prostaglandin production.

Glucocorticoids may also regulate the expression of COX-2 and stimulate the release of annexin A1. Effects of glucocorticoids on other cells may also reduce neutrophil responses indirectly through the suppression of cytokines at inflammatory sites.

Other anti-inflammatory/immunomodulatory agents also have well-established effects on neutrophils. Methotrexate, widely used in rheumatoid arthritis, has no direct neutrophil effect but is capable of producing indirect effects, probably by virtue of its ability to stimulate the release of adenosine from surrounding cells. Some data suggest that methotrexate-induced adenosine release might inhibit phagocytosis, O_2^- production, and adhesion¹⁰² and that treatment of patients with methotrexate inhibits the capacity of neutrophils to generate LTB_4 .

Colchicine, a standard agent in the treatment of gout and familial Mediterranean fever, inhibits microtubule formation and has pleiotropic effects on neutrophils including inhibition of adhesion via decrements in selectin expression.¹⁰³ Colchicine has been observed to stimulate the expression of pyrin in neutrophils. Because pyrin deficiencies are implicated in familial Mediterranean fever, this observation suggests a previously unappreciated mechanism of action of colchicine in neutrophilic diseases.

Sulfasalazine has been shown to inhibit neutrophil responsiveness to chemoattractants; to inhibit chemotaxis, degranulation, and O_2^- production; to decrease LTB_4 production; and to scavenge oxygen metabolites. Similar to sulfasalazine, gold salts may scavenge toxic metabolites. Gold salts, still in use for rheumatoid arthritis in some parts of the world, also decrease neutrophil collagenase activity and reduce E-selectin expression on endothelium.⁹⁹

The current era of biologic therapies has been ushered in through the introduction of agents designed to block the effects of TNF or IL-1. As noted earlier, IL-1 and TNF directly affect neutrophil function including priming for stimulus-induced responses such as O_2^- production, cartilage destruction, and production of cytokines such as IL-8 and LTB_4 . Nonetheless, studies examining the effects of anti-TNF treatment on neutrophil function measured ex vivo have not indicated extensive action. Treatment of patients with etanercept¹⁰⁴ or adalimumab¹⁰⁵ induced no effect on neutrophil ex vivo responses including chemotaxis, phagocytosis, and superoxide generation (although CD69 levels were reduced). Reduction of neutrophil populations in rheumatoid arthritis joint effusions after anti-TNF therapy is more likely due to alteration of the inflammatory environment, rather than to direct effects on the neutrophils themselves.

Eosinophils

JOSE U. SCHER • STEVEN B. ABRAMSON •
MICHAEL H. PILLINGER

KEY POINTS

Eosinophils are myeloid-lineage cells that contain many cytoplasmic granules consisting of proteins such as major basic protein, eosinophil cationic protein, eosinophil-derived neurotoxin, and eosinophil peroxidase.

Eosinophils are thought to function in the defense of helminths and other parasites. However, evidence for such an antihelminthic role is limited.

In contrast to neutrophils, eosinophils are not primarily phagocytic cells but are thought to discharge their granule contents adjacent to larger organisms that may be their targets.

Eosinophilia may be seen in many rheumatic diseases, including Churg-Strauss syndrome, eosinophilic fasciitis, and the idiopathic hypereosinophilic syndromes.

The eosinophil line shares many features with the other families of polymorphonuclear granulocytes. In contrast to the neutrophil, however, the eosinophil is primarily a tissue-localized cell. Eosinophils are produced in numbers smaller than neutrophils, and their half-life in the blood is shorter (3 to 8 hours) owing to higher rates of diapedesis. Normal bloodstream levels of eosinophils tend to be low—typically less than 5% of blood leukocytes. When in the tissues, eosinophils are longer-lived than neutrophils, with estimates ranging from 2 to 14 days. Tissue eosinophils are found in greatest concentrations in gastrointestinal mucosa, suggesting that they participate in barrier rather than bloodstream surveillance.

EOSINOPHIL DEVELOPMENT AND MORPHOLOGY

Similar to neutrophils, eosinophils follow a classic pattern of granulocyte differentiation, passing through blast, promyelocyte, myelocyte, metamyelocyte, and band stages before reaching maturity. Along the way, eosinophils successively acquire morphologically distinct classes of granules. Factors required for eosinophil differentiation include granulocyte-macrophage colony-stimulating factor (GM-CSF) and interleukin (IL)-3, which also are required for neutrophil differentiation and cannot account for eosinophil commitment. An essential role for IL-5 in eosinophil development has been described, supported by the observation that intravenous administration of IL-5 rapidly results in peripheral eosinophilia. IL-5 may not be completely eosinophil specific, however, because studies in animal models suggest that it is also trophic for B cells. Similar to IL-5, IL-2 can

stimulate eosinophilia. The IL-2 effect seems to be mediated through production of IL-5, however. CCL11 (eotaxin-1) also may cause bone marrow release of mature eosinophils and eosinophil precursors via engagement of CCR3 receptors, which are expressed mainly on eosinophils.¹ Cooperation between IL-5 and eotaxins, in particular eotaxin-1, seems to be needed to induce tissue eosinophilia. Knockout mice with targeted deletion of CCR3 show deficiency in gastrointestinal eosinophils. Several transcription factors are involved in the eosinophilic lineage commitment, including the CCAAT/enhancer binding protein family (C/EBB) members, the interferon consensus sequence binding protein (ICSBP), and GATA-1.

When viewed under hematoxylin and eosin staining, eosinophils appear slightly larger than neutrophils (12 to 17 μ m). Their nuclei typically are bilobed. Most striking is the presence of large, pink-staining granules. In addition, lipid bodies occasionally may be seen—nonvesicular accumulations of arachidonic acid and other lipids, presumably liberated from plasma membrane. These are not unique, however, and may be detected occasionally in neutrophils as well.

Eosinophils contain at least three distinguishable classes of granules (Table 12-1). Primary granules form first and are analogous to the primary (azurophilic) granules of neutrophils. In contrast to neutrophils, eosinophil primary granules lack myeloperoxidase. Eosinophil primary granules are most numerous in eosinophilic promyelocytes and persist in smaller numbers in mature forms. In mature eosinophils, a lysophospholipase that is present in large quantities (7% to 10% of total eosinophil protein) has been tentatively localized to primary granules, which when released extracellularly precipitates into bipyramidal structures known as *Charcot-Leyden crystals*. Deposition of these crystals in tissues is taken as evidence of present or past eosinophilia.

The large granules visible in mature eosinophils are specific granules that form during the myelocyte stage. When viewed under scanning electron microscopy, specific granules show a dense crystalline core surrounded by an intermediate-density matrix. Because of their large size and number (>90% of overall granule population), eosinophil specific granules have yielded to isolation and immunocytochemical examination, and their contents have been at least partially evaluated. Among the contents probably localized to specific granules are lysosomal enzymes (acid and neutral hydrolases, collagenase, cathepsin, and gelatinase), lectins, and components of the oxidase system. Most distinct is the presence of four highly basic proteins that lend the granule its tinctorial properties. Major basic protein (MBP), an 11,000-kD protein with an isoelectric point

Table 12-1 Eosinophil Granule Contents

	Arylsulfatase Granules	Primary Granules	Specific Granules
Relative size	Smallest	Intermediate	Largest
Contents	Arylsulfatase Acid phosphatase	Lysophospholipase	Major basic protein Eosinophil cationic protein Eosinophil-derived neurotoxin Eosinophil peroxidase Acid hydrolases Neutral hydrolase Collagenase Cathepsin Gelatinase

value of 11, accounts for more than 50% of the total granule protein and is the major, or possibly sole, component of the crystalline core. Eosinophil cationic protein (ECP), actually a heterogeneous group of several related proteins (18 to 21 kD molecular weight), also is present in large amounts (up to 10% on weight/weight basis).

Eosinophil-derived neurotoxin (EDN) (18 kD molecular weight), the third of the basic granular proteins, is slightly less basic (isoelectric point 8.9) than the aforementioned proteins and is present in smaller quantities. In contrast to MBP and ECP, which have likely roles in host defense, EDN is mainly recognized for its function as a neurotoxin for myelinated neurons, the evolutionary advantage of which is unclear. The *Gordon phenomenon*, in which injection of eosinophil-laden tissue into an animal produces profound neurologic deficits, is likely due to eosinophil-derived neurotoxin. It has been shown that EDN serves as an endogenous ligand of TLR2, can activate Myd88 in dendritic cells, and shifts adaptive immunity toward a T helper (Th)-2 response, suggesting a pivotal role for eosinophils in the innate-adaptive immune response.² Finally, eosinophil specific granules contain large quantities of eosinophil peroxidase, an enzyme distinctly different from neutrophil myeloperoxidase, but probably subsuming the same function of generating hypohalides for cell killing and activation of latent proteinases. ECP, EDN, and eosinophil peroxidase are localized within the primary granule matrix region. A third population of smaller eosinophilic granules has been identified by virtue of its acid phosphatase and arylsulfatase B content and is present mainly in tissue eosinophils.

EOSINOPHIL ACTIVATION AND DISTRIBUTION

Similar to neutrophils, eosinophils undergo activation in response to stimuli and are capable of adhesion, chemotaxis, phagocytosis, degranulation, and O_2^- generation. Eosinophils respond to many of the same chemoattractant stimuli as neutrophils, although with different sensitivities. In addition, eosinophils respond to stimuli that do not affect

neutrophils, including IL-3, IL-5, regulation upon activation normal T cell expressed and presumably excreted (RANTES), and macrophage inflammatory protein (MIP)-1 α . Whether the distribution of these factors is sufficient to explain the tissue distribution of eosinophils relative to other granulocytes is uncertain; however, eosinophils and mast cells secrete IL-3 and IL-5, suggesting their capacity to attract additional eosinophils to sites of atopy. Eosinophils express not only adhesion molecules identified on neutrophils—CD11a/CD18, CD11b/CD18, and L-selectin—but also others, such as the $\alpha 4\beta 1$ integrin VLA-4. IL-4 and IL-13 induce expression of the VLA-4 counterligand, vascular cell adhesion molecule (VCAM)-1, via an eotaxin-1, STAT6-dependent pathway. Oncostatin-M, an IL-6/gp130 family member, also seems to upregulate VCAM-1 in an eotaxin-1, STAT6-dependent manner, and to play a role in eosinophil accumulation in a mouse model.³

Eosinophils also differ from neutrophils in their repertoire of immunoglobulin receptors. Although eosinophils possess immunoglobulin (Ig)G receptors, these are relatively sparse. Instead, the predominant immunoglobulin receptors on the eosinophil surface are high affinity for IgA, consistent with the role of the eosinophil in barrier defense. Although eosinophils are activated by IgG and IgA, they are most potently activated by secretory IgA, probably owing to the presence of a receptor unique for the secretory component. In contrast to earlier teaching, expression of IgE receptors on eosinophils surfaces is minimal and most likely is of little biologic significance.

NORMAL EOSINOPHIL FUNCTION

Although some studies have demonstrated the capacity of eosinophils to phagocytose bacteria, others suggest that these cells phagocytose poorly, and it is likely that antibacterial defense is not a primary eosinophil function. Instead, eosinophils most likely participate in host defense against multicellular, helminthic parasites; eosinophilia typically occurs in response to parasitic but not bacterial infection. Eosinophils can phagocytose small parasitic forms but more characteristically attach, in a polarized manner, to the surface of larger parasites and discharge their granular contents into the protected space between the parasite and the eosinophil. Although O_2^- generation and proteinase release may play a role in this attack, the specific granule-associated basic proteins are probably the major weapon in the anti-parasitic armamentarium of the eosinophil. In vitro studies have shown the capacities of these proteins, particularly ECP and MBP, to kill protozoa. Although ECP is ≈ 10 -fold more potent, the higher concentration of MBP present in the granules suggests that it is the dominant parasite toxin. Parasitic killing by each of the proteins seems to depend on its capacity to disrupt the plasma membrane; in the case of ECP, membrane disruption occurs through the formation of pores or channels. More recently, it has been shown that similar to neutrophils, eosinophils are able to generate extracellular traps with bactericidal properties.⁴ In response to bacterial exposure—C5a or CCR3—eosinophils rapidly release mitochondrial DNA and granule proteins. In contrast to neutrophils, eosinophils do not undergo apoptosis upon release of their DNA, and their traps are composed

mainly of ECP and MBP. Eosinophils (similar to neutrophils) have been reported to present antigen to T cells; it is not established whether antigen presentation plays any role in the antiparasitic effect. Although epidemiologic and in vitro evidence supports a role for eosinophils in parasitic defense, in vivo confirmation of such a role is equivocal. In particular, several studies indicate that eosinophil ablation (through IL-5 depletion) has no effect on the course of parasite infection in mice. This might reflect redundancy of antiparasitic defenses.

EOSINOPHIL RELEVANCE TO INFLAMMATORY AND AUTOIMMUNE DISEASE

Asthma

Although not strictly a rheumatic disease, asthma represents the most common inflammatory/autoimmune disease in which eosinophils predominate. Although the presence of blood and pulmonary eosinophilia in asthma has been appreciated for a century, the role of eosinophils in the pathogenesis of this disease remains a subject of intense study. Eosinophilia in asthma is stimulated by high levels of IL-5 and other cytokines. Eosinophils possess multiple mechanisms through which they can, at least potentially, enhance the asthmatic response. Similar to neutrophils, stimulated eosinophils synthesize leukotriene (LT) A_4 from arachidonic acid. In contrast to neutrophils, however, eosinophil metabolism of LTA $_4$ leads to the production not of LTB $_4$, but of LTC $_4$ and LTD $_4$ (cysteinyl leukotrienes)—both potent bronchoconstrictors.⁵ Eosinophils themselves are exquisitely sensitive to the effects of cysteinyl leukotrienes, which stimulate eosinophil adhesion, migration, and degranulation and the proliferation of eosinophil progenitors. The cysteinyl leukotriene receptor antagonists (lukasts) are effective in the treatment of asthma and have been shown to have direct effects on eosinophils in vivo and in vitro, including reduction of eosinophil transmigration and reduction of pulmonary and peripheral eosinophilia.⁶ Lukasts seem to have beneficial effects on other diseases characterized by eosinophilia, including cystic fibrosis, eosinophilic gastroenteritis, and atrophic dermatitis.

Platelet-activating factor is produced by stimulated eosinophils and has bronchoconstricting activities. Release of specific granule proteins per se has multiple proasthmatic effects, including (1) epithelial damage secondary to membrane perturbations similar to those seen in parasites, and (2) activation of mast cells with subsequent histamine and leukotriene production. MBP also may act specifically as an antagonist of muscarinic M2 receptors, resulting in enhanced vagal tone and increased bronchospasm.⁷

Rheumatic Diseases

Although hypereosinophilia occasionally can be observed in virtually all rheumatic diseases, it is relatively uncommon in most, perhaps owing in part to the widespread use of corticosteroid therapy.⁸ In Churg-Strauss vasculitis, hypereosinophilia is the classic laboratory abnormality accompanying a constellation of pulmonary and renal vasculitis and asthma. In some cases, peripheral eosinophil counts in

Churg-Strauss vasculitis have been reported to exceed 50% of total leukocytes. The cluster of asthma and eosinophilia accompanying Churg-Strauss vasculitis suggests that this syndrome may represent an atopic response to a foreign antigen. IgE response varies, however, and asthma may precede the rest of the disease by years. The presence of antimyeloperoxidase antibody (perinuclear antineutrophil cytoplasmic antibody [ANCA]), an IgG class antibody, is common, suggesting a broader autoimmune response. Systemic steroids with or without cyclophosphamide, followed by steroid-sparing agents remain the mainstream therapeutic options. Anti-IgE therapy with omalizumab⁹ and anti-IL-5 antibodies (mepolizumab)¹⁰ have been tried with mixed results.

Eosinophilia-myalgia syndrome was first observed in 1989 in New Mexico and was defined by the Centers for Disease Control and Prevention for surveillance purposes as peripheral eosinophilia and muscle pains unexplained by other illnesses. Rash and skin edema are common findings. Follow-up of cases over time revealed the frequent appearance of fibrosing fasciitis, which, in more severe disease, results in skin retraction, particularly over the veins, where it gives rise to a train-track appearance. Intensive epidemiologic investigation pinpointed the likely cause of the epidemic as consumption of L-tryptophan supplements produced by a single manufacturer, probably owing to trace contaminants. Discontinuation of the sale of the supplement led to resolution of the epidemic, although sporadic tryptophan-independent cases continue to be reported. Eosinophilic fasciitis, a condition first described in 1975, resembles eosinophilia-myalgia syndrome in that it involves fasciitis and eosinophilia but differs in that myalgias are not a prominent feature, and organ involvement is unusual. Clinically, the skin of patients with eosinophilic fasciitis bears some resemblance to the skin of patients with systemic sclerosis, but the distribution is typically on the distal extremities with sparing of the hands and feet. An epidemic similar to eosinophilia-myalgia syndrome was seen in Spain in 1981, related to consumption of adulterated rapeseed oil (toxic oil syndrome). Although in these syndromes it is unclear whether eosinophils act as mediators of fasciitis or merely as reporters of exposure to an atopic antigen, the capacity of eosinophils to produce transforming growth factor (TGF)- β suggests a potential role for these cells in the generation of fibrous tissue. The presence of eosinophils in affected tissues varies, however, with most infiltrates consisting of other leukocytes.

A single study has shown indirect evidence for the presence of increased numbers of eosinophils (Charcot-Leyden crystal deposition) in progressive systemic sclerosis. The relevance of this observation remains to be determined.

Primary Eosinophilic Syndromes

Idiopathic hypereosinophilic syndrome (HES) has been defined as (1) persistent eosinophils numbering 1500/mm³ for 6 or more months (or until death); (2) absence of parasites, allergy, or other causes of eosinophilia; and (3) signs and symptoms of organ involvement related directly to eosinophils or eosinophil accumulation. Morbidity is largely associated with eosinophil tissue infiltration, and granuloma formation may occur. Idiopathic hypereosinophilic

syndrome has gained attention with the description of patients with a genetic rearrangement, del^4 (q12q12), that results in fusion of the platelet-derived growth factor receptor- α (*PDGFR α*) and Fip1-like 1 (*FIP1L1*) genes, generating a novel, constitutively active tyrosine kinase responsible for the clonal expansion of eosinophils. Targeted therapy with the selective tyrosine kinase inhibitor imatinib has become an effective tool in many cases of hypereosinophilic syndrome associated with the *FIP1L1-PDGFR α* fusion gene.¹¹ A few placebo-controlled trials indicated that mepolizumab, an anti-IL-5 monoclonal antibody, also might offer clinical benefit and steroid-sparing effects.¹² In a subset of patients with refractory HES, alemtuzumab, a monoclonal anti-CD52 antibody, lowers eosinophilia and induces remission.¹³ To date, corticosteroids remain the primary treatment for idiopathic hypereosinophilic syndrome.

Eosinophilic esophagitis (EE) is a more recently recognized entity defined by the accumulation of eosinophils in the esophagus, which, in contrast to gastroesophageal reflux disease, does not respond to therapy with proton pump inhibitors. Patients with eosinophilic esophagitis are predominantly young men who have high levels of eosinophils in the esophageal mucosa, extensive hyperplasia, a high rate of atopic disease, and normal pH monitoring compared with patients with gastroesophageal reflux disease. The prevalence seems to be increasing, notably among whites from Western countries.¹⁴ Recent studies suggest that human EE is driven by upregulation of eotaxin-3 in esophageal epithelial cells, which acts as a potent eosinophil chemoattractant.¹⁵ Oral fluticasone propionate and mepolizumab have proved effective in initial trials.

Löffler's syndrome is a self-limiting eosinophilic pneumonitis with peripheral eosinophilia, presumably a hypersensitivity reaction. Allergic bronchopulmonary aspergillosis also represents a hypersensitivity reaction and may be indistinguishable from Löffler's syndrome. A novel eosinophilic syndrome has been described, consisting of nodules, eosinophilia, rheumatism, dermatitis, and swelling (NERDS); because only a few cases have been reported to date, the clinical identity of this illness awaits validation.

Addison's Disease

Addison's disease is a disorder of adrenal failure resulting in underproduction of steroid hormones. Addison's disease frequently is accompanied by peripheral eosinophilia. In contrast to increases in peripheral neutrophil counts, the ability of glucocorticoids to reverse the eosinophilia of Addison's disease implicates that class of agents as a key regulator in the downregulation of eosinophil number. Glucocorticoids rapidly reduce eosinophil numbers in most hypereosinophilic and nonhypereosinophilic patients—a

fact enshrined in the clinical maxim that detectable levels of eosinophils in a patient on long-term glucocorticoid therapy may be evidence of noncompliance with medication. Whether glucocorticoids have an effect on eosinophil production, release, or survival remains to be determined. Regardless of the mechanism of their effect, use of glucocorticoids to reduce eosinophil count is an important strategy in reducing morbidity from hypereosinophilic diseases.

T Lymphocytes

RALPH C. BUDD • KAREN A. FORTNER

KEY POINTS

T cells develop primarily in the thymus. The importance of the thymus is underscored by the complete absence of T cells in patients in whom a thymus has failed to develop (e.g., complete DiGeorge syndrome).

Thymic selection consists of a positive phase in which T cells must recognize self-MHC molecules, and a negative phase in which thymocytes bearing high-affinity TCRs for self-MHC peptide are deleted through apoptosis.

T cells emerge from the thymus as naïve T cells that are quiescent and, when activated, express low to negligible levels of most cytokines. Once they acquire a memory phenotype (CD45RO⁺), they can produce high levels of cytokines.

Naïve T cells can spontaneously undergo homeostatic proliferation to self-MHC peptides in peripheral lymphoid tissues to generate a critical number of T cells. This requires IL-7 and IL-15.

Th1 and Th17 cells accumulate in inflammatory synovium such as rheumatoid arthritis, whereas Th2 cells accumulate at sites of allergic responses such as asthma.

OVERVIEW

The evolutionary pressures that have molded the immune response and promoted a highly diverse repertoire clearly derive from infectious agents. Two different strategies exist. The more primitive innate immune response (see Chapter 18) uses a limited repertoire of nonpolymorphic receptors that recognize structural motifs that are common to many microorganisms. These include small glycolipids and lipopeptides. The alternative strategy of the evolutionarily newer adaptive immune response (see Chapter 19) relies on generating myriad different receptors that can recognize a wide array of foreign compounds from infectious agents. Whereas the innate immune response allows a rapid focused response, adaptive immunity permits a broader, albeit slower, response but critically offers the additional benefit to the host of immune memory.

T lymphocyte development constantly confronts the dilemma of combating infection without provoking a response to the host. The price for generating an increasingly varied population of antigen receptors needed to recognize a wide spectrum of pathogens is the progressive risk of producing self-reactive lymphocytes that can provoke an

autoimmune diathesis. To minimize the possibility of self-reactive cells, T lymphocytes are subjected to a rigorous selection process during development in the thymus. In addition, premature activation of mature T cells is prevented by requiring two signals for activation. Finally, the tremendous expansion of T cells that occurs during the response to an infection is resolved by the active induction of cell death. The consequences of inefficient lymphocyte removal at any one of these junctures can be devastating to the health of the organism. This is vividly displayed in both humans and mice where naturally arising mutations in death receptors such as Fas result in massive accumulation of lymphocytes and autoimmune sequelae. These are discussed in more detail in Chapter 27 on cell survival and death.

The activation of T lymphocytes yields a variety of effector functions that are pivotal to combating infections. Cytolytic T cells can kill infected cells through the expression of perforin, which induces holes in cell membranes, or ligands for death receptors such as Fas or tumor necrosis factor (TNF) receptor. Production of T cell cytokines such as interferon- γ (IFN- γ) can inhibit viral replication, whereas other cytokines such as interleukin (IL)-4, IL-5, and IL-21 are critical for optimal B cell growth and immunoglobulin production.¹ However, this same armamentarium, if not tightly regulated, can also precipitate damage to host tissues and provoke autoimmune responses. This is particularly apparent in situations where T cell infiltration can be observed histologically such as in the synovium of inflammatory arthritides, pancreatic islets in type 1 diabetes, and the central nervous system in multiple sclerosis. Damage in these cases need not be the direct result of recognition of target tissues by the T cells. T cells may be activated elsewhere and then migrate to the tissue and damage innocent bystander cells. T cells may also promote autoimmunity through the augmentation of B cell responses.

T CELL DEVELOPMENT

T cells must traverse two stringent hurdles during their development. First, they must successfully rearrange the genes encoding the two chains of the T cell antigen receptor (TCR). Second, T cells must survive thymic selection during which T cells that interact strongly with self-peptides are eliminated. This minimizes the chances of autoreactive T cells escaping to the periphery.

The TCR is an 80- to 90-kD disulfide-linked heterodimer composed of a 48- to 54-kD α chain and a 37- to 42-kD β chain. An alternate TCR composed of γ and δ chains is expressed on 2% to 3% of peripheral blood T cells and is

discussed later. The TCR has an extracellular ligand binding pocket and a short cytoplasmic tail that by itself cannot signal. Consequently it is noncovalently associated with as many as five invariant chains of the CD3 complex that relay information to the intracellular signaling machinery via immunoreceptor tyrosine activation motifs (ITAMs) (see later). Not surprisingly, the structure of the TCR gene is similar to what was first described for immunoglobulin genes in B cells (see details in Chapter 14). Each overcame the problem of how to encode approximately 10 million different T or B cell specificities within the human genome, which contains only 30,000 genes. To economically package this diversity, the process of gene rearrangement and splicing evolved using machinery similar to that which already existed to promote gene translocations. The β and δ chain genes of the TCR contain four segments known as the *V* (*variable*), *D* (*diversity*), *J* (*joining*), and *C* (*constant*) regions. The α and γ chains are similar but lack the *J* component. Each of the segments has several family members (≈ 50 to 100 *V*, 15 *D*, 6 to 60 *J*, and 1 to 2 *C* members). An orderly process occurs during TCR gene rearrangement in which a *D* segment is spliced adjacent to a *J* segment, which is subsequently spliced to a *V* segment.

Following transcription, the VDJ sequence is spliced to a *C* segment to produce a mature TCR messenger RNA. Arithmetically, this random rearrangement of a single chain of the TCR locus can give rise to a minimum of $50V \times 15D \times 6J \times 2C$, or about 9000 possible combinations. At each of the splice sites, which must occur in-frame to be functional, additional nucleotides not encoded by the genome (so-called *N-region nucleotides*) can be incorporated, adding further diversity to the rearranging gene. The combinations from the two TCR chains, plus *N-region* diversity, yield at least 10^8 possible combinations. Cutting, rearranging, and splicing are directed by specific enzymes. Mutations in the genes mediating these processes can result in arrest in lymphocyte development. For example, mutation in the gene encoding a DNA-dependent protein kinase required for receptor gene recombination results in a severe combined immunodeficiency (SCID).

Because the developing T cell has two copies of each chromosome, there are two chances to successfully rearrange each of the two TCR chains. As soon as successful rearrangement occurs, further β -chain rearrangements on either the same or the other chromosome are suppressed, a process known as *allelic exclusion*. This limits the chance of dual TCR expression by an individual T cell. The high percentage of T cells that contain rearrangements of both β -chain genes attests to the inefficiency of this complex event. Rearrangement of the α chain occurs later in thymocyte development in a similar fashion, although without apparent allelic exclusion. This can result in dual TCR expression by a single T cell.

Development of T cells occurs within a microenvironment provided by the thymic epithelial stroma. The thymic anlage is formed from embryonic ectoderm and endoderm and is then colonized by hematopoietic cells, which give rise to dendritic cells, macrophages, and developing T cells.² The hematopoietic and epithelial components combine to form two histologically defined compartments: the cortex, which contains immature thymocytes, and the medulla, which contains mature thymocytes (Figure 13-1A). As few

as 50 to 100 bone marrow–derived stem cells enter the thymus daily.

The stages of thymocyte development can be defined by the status of rearrangement and expression of the two genes that encode the α and β chains of the TCR and the expression of CD4 and CD8, proceeding in an orderly fashion from $CD4^{-}8^{-} \rightarrow CD4^{+}8^{+} \rightarrow CD4^{+}8^{-}$ or $CD4^{-}8^{+}$ (Figure 13-1B). CD4 and CD8 define, respectively, the helper and cytolytic subsets of mature T cells.

$CD4^{-}8^{-}$ thymocytes can be further subdivided based on their expression of CD25 (the high-affinity IL-2 receptor α chain) and CD44 (the hyaluronate receptor).³ Development proceeds in this order: $CD25^{-}CD44^{+} \rightarrow CD25^{+}CD44^{+} \rightarrow CD25^{+}CD44^{-} \rightarrow CD25^{-}CD44^{-}$. These subpopulations correspond to discrete stages of thymocyte differentiation. $CD25^{+}44^{+}$ cells express low levels of CD4, and their TCR genes are in germline configuration. These cells downregulate CD4 and upregulate CD25 to give rise to $CD25^{+}CD44^{+}$ thymocytes, which now express surface CD2 and low levels of CD3 ϵ . At the next stage ($CD25^{+}CD44^{-}$), there is a brief burst of proliferation followed by upregulation of the recombination-activating enzymes, RAG-1 and RAG-2, and the concomitant rearrangement of the genes of the TCR β chain. A small subpopulation of T cells rearranges and expresses a second pair of TCR genes known as γ and δ . Productive TCR β -chain rearrangement results in downregulation of RAG and a second proliferative burst. Loss of CD25 then yields $CD25^{-}CD44^{-}$ thymocytes.

The TCR β chain cannot be stably expressed without an α chain. Because the TCR α chain has not yet rearranged, a surrogate invariant TCR pre- α chain is disulfide linked to the β chain.⁴ When associated with components of the CD3 complex, this allows a low-level surface expression of a pre-TCR and progression to the next developmental stage. Failure to successfully rearrange the TCR β chain results in a developmental arrest at the transition from $CD25^{+}CD44^{-}$ to $CD25^{-}CD44^{-}$. This occurs in RAG-deficient mice, as well as in mice and humans with SCID.⁵

A number of signaling molecules are required for early T cell development (Figure 13-2). The *Ikars* gene encodes a family of transcription factors required for the development of cells of lymphoid origin. Notch-1, a molecule known to regulate cell fate decisions, is also required at the earliest stage of T cell lineage development.⁶ Cytokines including IL-7 promote the survival and expansion of the earliest thymocytes. In mice deficient for IL-7, its receptor components IL-7R α or γ_c , or the cytokine receptor–associated signaling molecule JAK-3, thymocyte development is inhibited at the $CD25^{-}CD44^{+}$ stage. In humans, mutations in γ_c or JAK-3 result in the most frequent form of SCID.⁷ Pre-TCR signaling is required for the $CD25^{+}CD44^{-} \rightarrow CD25^{-}CD44^{-}$ transition. Thus loss of signaling components including Lck, SLP-76, and LAT-1 results in a block at this stage of T cell development. TCR signals are also required for differentiation of $CD4^{+}CD8^{+}$ to $CD4^{+}$ or $CD8^{+}$ cells. Humans deficient in ZAP-70 (see later) have $CD4^{+}$ but not $CD8^{+}$ T cells in the thymus and periphery.⁸

$CD25^{-}CD44^{-}$ cells upregulate expression of CD4 and CD8 to become $CD4^{+}8^{+}$. It is as a $CD4^{+}CD8^{+}$ thymocyte that the α chain of the TCR rearranges. Unlike the β chain, allelic exclusion of the α chain is not apparent. Rearrangement of the α chain can occur simultaneously on both

Figure 13-1 Sequence of thymocyte development. **A**, The earliest thymocyte precursors lack expression of CD4 and CD8 ($CD4^-CD8^-$). These can be further divided into four subpopulations based on sequential expression of CD44 and CD25. It is at the $CD44^+CD25^+$ stage that the TCR- β -chain rearranges. The SCID mutation or deficiencies of the rearrangement enzymes Rag-1 and Rag-2 result in inability to rearrange the β -chain and maturational arrest at this stage. Those thymocytes that successfully rearrange the β -chain express it associated with a surrogate α -chain known as pre-T α . Concomitant with a proliferative burst, development can then progress to the $CD4^+CD8^+$ stage in the cortex where the TCR- α -chain rearranges and pairs with the β -chain to express a mature TCR complex. These cells then undergo thymic positive and negative selection (as diagrammed in Figure 13-3B). Successful completion of this rigorous selection process results in mature $CD4^+$ or $CD8^+$ T cells in the medulla, which eventually emigrate to peripheral lymphoid sites. **B**, Schematic two-color flow cytometry showing subpopulations of thymocytes defined by CD4 and CD8 expression in their relative proportions.

chromosomes, and if one attempt is unsuccessful, repeat rearrangements to other V α segments are possible. Reports exist of dual TCR expression by up to 30% of mature T cells in which the same T cell expresses different α chains paired with the same β chain.⁹ However, in most cases of dual TCR α chains, one is downregulated during positive selection by Lck and Cbl, through ubiquitination, endocytosis, and degradation.

Although the structure of immunoglobulin and TCR are quite similar, they recognize fundamentally different antigens. Immunoglobulins recognize intact antigens in isolation, either soluble or membrane bound, and are often sensitive to the tertiary structure. The TCR $\alpha\beta$ recognizes linear stretches of antigen peptide fragments bound within the grooves of either major histocompatibility complex (MHC) class I or class II molecules (Figure 13-3A). Thymic selection molds the repertoire of emerging TCR so that they recognize peptides within the groove of self-MHC molecules, ensuring *self-MHC restriction* of T cell responses. The MHC structure is described in detail in Chapters 19 through 21. Pockets within the MHC groove bind particular residues along the peptide sequence of 7 to 9 amino acids for MHC class I and 9 to 15 amino acids for MHC class II molecules. As a result, depending on the particular MHC molecule, certain amino acids will make strong contact with the MHC groove while others will contact the TCR.

The contact between the TCR and MHC/peptide has been revealed by crystal structure to be remarkably flat, rather than a deep lock and key structure one might imagine.¹⁰ The TCR axis is tipped about 30 degrees to the long axis of the MHC class I molecule and is slightly more skewed to MHC class II. The affinity of the TCR for antigen/MHC is in the micromolar range. This is less than many antibody-antigen affinities and is several logs less than many enzyme-substrate affinities. This has led to the notion that TCR interactions with antigen/MHC are brief and that successful activation of the T cell requires multiple interactions, resulting in a cumulative signal.

Once the T cell has successfully rearranged and expressed a TCR in association with the CD3 complex, it encounters the second major hurdle in T cell development, *thymic selection*. Selection has two phases, positive and negative, and the outcome is based largely on the intensity of TCR signaling in response to interactions with MHC/self-peptides expressed on thymic epithelium and dendritic cells. TCR signals that are either too weak (death by neglect) or too intense (*negative selection*) result in elimination by apoptosis, whereas those with intermediate signaling intensity survive *positive selection* (Figure 13-3B). Successful positive selection at the $CD4^+8^+$ stage is coincident with upregulation of surface TCR, the activation markers CD5 and CD69, and the survival factor Bcl-2.¹¹ T cells bearing a TCR that

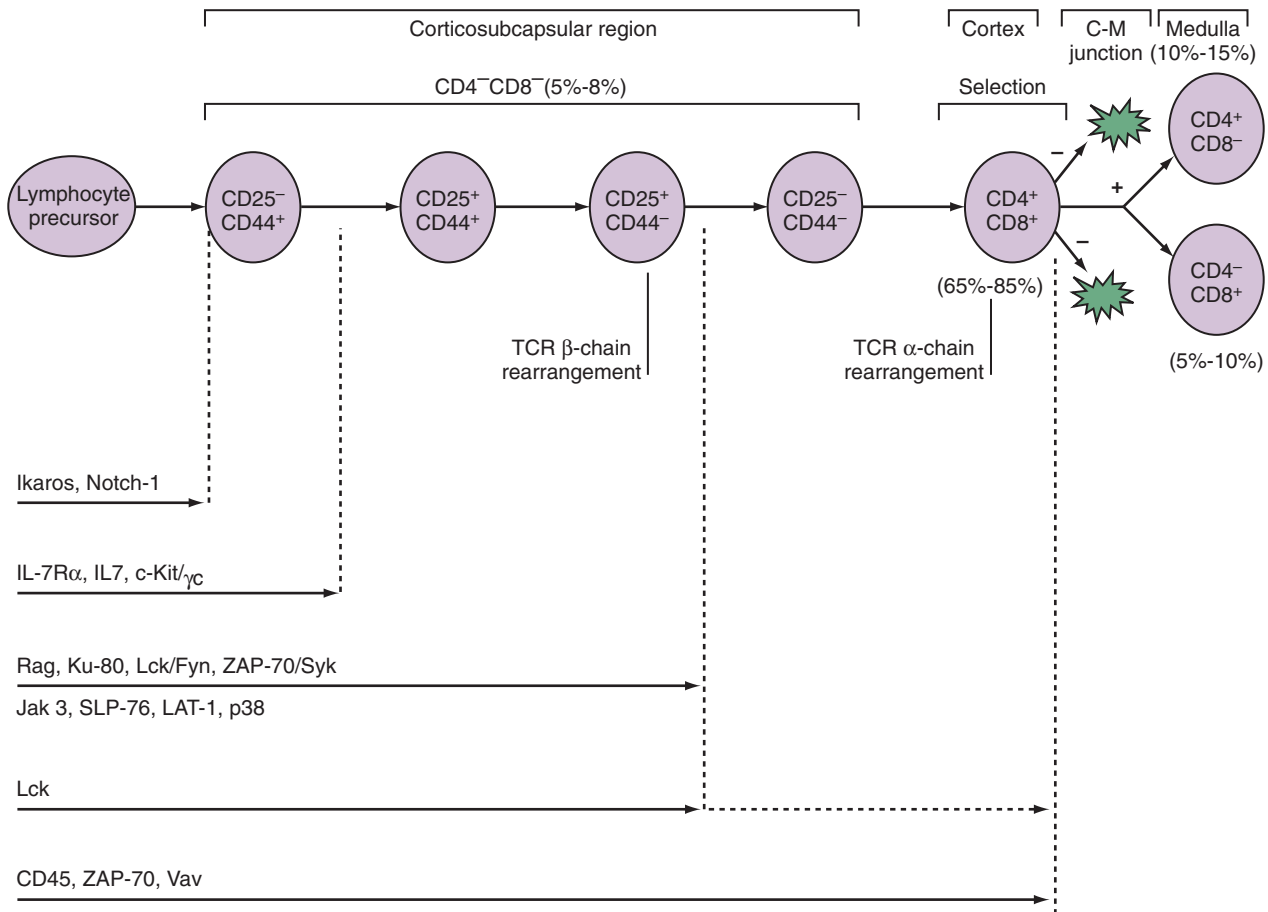

Figure 13-2 Sequence of $\alpha\beta$ T cell development in the thymus. The earliest thymocyte precursors lack expression of CD4 and CD8 (CD4⁻CD8⁻). These can be further divided into four subpopulations based on the sequential expression of CD25 and CD44. At the CD25⁺CD44⁻ stage, the TCR- β -chain rearranges and associates a surrogate α chain known as pre-T α . Concomitant with a proliferative burst, thymocytes progress to the CD4⁺CD8⁺ stage, rearrange the TCR- α -chain, and express a mature TCR complex. These cells then undergo thymic positive and negative selection. Those thymocytes that survive this rigorous selection process differentiate into mature CD4⁺ or CD8⁺ T cells. Shown also are the various signaling molecules that are involved at specific stages of thymic development.

recognizes MHC class I maintain CD8 expression, down-regulate CD4, and become CD4⁻CD8⁺. T cells expressing a TCR that recognizes MHC class II become CD4⁺CD8⁻.

An enigma for thymic selection has been how to present the myriad self-proteins to developing thymocytes so that self-reactive thymocytes are effectively eliminated by negative selection. This includes particularly those antigens with tissue or developmentally restricted expression. A solution was found with the discovery of the autoimmune regulator (AIRE) gene. AIRE is a transcription factor expressed by the medullary epithelium of the thymus that induces transcription of a wide array of organ-specific genes, such as insulin, that might otherwise be sequestered from developing thymocytes.¹² This effectively creates a self-transcriptome within the thymus against which autoreactive T cells can be deleted. Gene knockout mice of AIRE and humans bearing AIRE mutations manifest various autoimmune sequelae in a syndrome known as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED).¹³

Not surprisingly, a variety of signaling molecules activated by TCR engagement are important to thymic selection. Lck, the Ras/Raf-1/MEK1/ERK kinase cascade, the kinase ZAP-70, and the phosphatases CD45 and

calcineurin are involved with positive selection. Among these the Ras/ERK pathway is particularly important because dominant negative variants of these molecules can disrupt positive selection. Conversely, an activator of Ras known as GRP1 assists the positive selection of thymocytes expressing weakly selecting signals. These molecules are discussed in more detail in the section on TCR signaling. By contrast, although a number of molecules may promote negative selection, among them the MAP kinases JNK and p38, there appears to be sufficient redundancy so that only rarely does elimination of any one of these molecules affect deletion of thymocytes. The few exceptions include CD40, CD40L, CD30, or the pro-apoptotic Bcl-2 family member, Bim, where preservation of at least some thymocytes bearing self-reactive TCR could be observed in mice deficient in these molecules.¹⁴⁻¹⁶

The survivors of these two stringent processes of TCR gene rearrangement and thymic selection represent less than 3% of total immature thymocytes. This is reflected in the presence of a high rate of cell death in developing thymocytes. This can be visualized by the measurement of DNA degradation, a hallmark of apoptosis, as shown in Figure 13-4. The survivors become either CD4⁺ helper or CD8⁺ cytolytic T cells and reside in the thymic medulla for

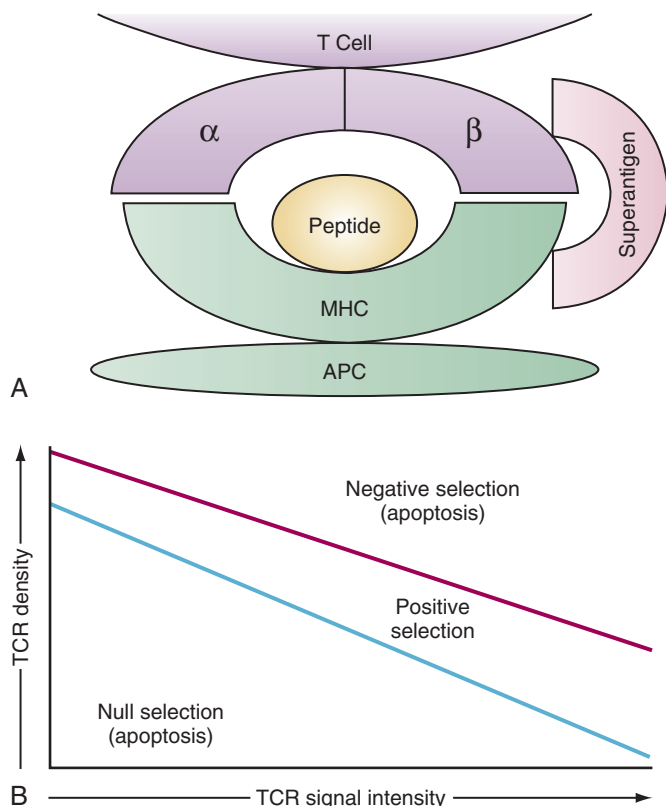

Figure 13-3 T cell antigen receptor (TCR) interaction with the major histocompatibility complex (MHC)–peptide complex. **A**, Polymorphic residues within the variable region of the α and β chains of the TCR make contact with determinants on the MHC molecule on an antigen-presenting cell (APC), as well as with the peptide fragment that sits in the MHC binding groove. **B**, Schematic diagram illustrating that during thymocyte development, those TCR conferring either a very low signal intensity (null selection) or high intensity (negative selection) each lead to apoptosis. Only those thymocytes whose TCR can engage MHC peptides and confer moderate intensity survive by positive selection.

12 to 14 days before emigrating to the periphery. The decision to become a $CD4^+$ versus $CD8^+$ T cell involves further developmental signals including once again Notch-1. Notch-1 signaling is required for progression to $CD8^+$ but not $CD4^+$ thymocytes. This parallels the observation that long TCR interactions are required for $CD4$ progression, whereas shorter TCR engagement is required for $CD8$ progression.¹⁷

Abnormalities of Human T Cell Development

Given the vast number of events in T cell development, it is not surprising that a multiplicity of causes can underlie human T cell immunodeficiencies.¹⁸ The influence of the thymic stroma on thymocyte ontogeny is underscored in the DiGeorge anomaly in which development of the pharyngeal pouches is disrupted and the thymic rudiment fails to form. This results in the failure of normal T cell development. Less severe T cell deficiencies are associated with a failure to express MHC class I and/or class II (the “bare lymphocyte syndrome”), which are directly involved with interactions required to induce the positive selection of, respectively, $CD8^+$ and $CD4^+$ mature T cells.

Metabolic disorders can affect thymocytes more directly. The absence of functional adenosine deaminase (ADA) and purine nucleoside phosphorylase (PNP) results in the buildup of metabolic by-products that are toxic to developing T and B lymphocytes. This ultimately produces forms of SCID.

The inability to express a number of surface molecules important in TCR and cytokine signaling also has the potential to perturb development. The failure to express TCR-CD3 components (specifically $CD3\gamma$ and $CD3\epsilon$), $CD18$, and $IL-2R\gamma$ have all been noted among patients who exhibit varying degrees of T cell deficiency or dysfunction.¹⁹ All these molecules are involved in signaling of thymocyte development and survival, and their absence clearly has the potential to alter developmental fate.

PERIPHERAL MIGRATION OF T CELLS

The migration of naïve T cells to peripheral lymphoid structures or their infiltration into other tissues requires the coordinate regulation of an array of cell adhesion molecules. T cell recirculation is essential for host surveillance and is carefully regulated by a specific array of homing receptors. Entry from the circulation to tissues occurs via two main anatomic sites: the flat endothelium of the blood vessels and specialized postcapillary venules known as *high endothelial venules* (HEV). A three-step model has been proposed for lymphocyte migration: rolling, adhesion, and migration.²⁰ L-selectin expressed by naïve T cells binds via lectin domains to carbohydrate moieties of GlyCAM-1 and CD34 (collectively known as *peripheral node addressin*) that are expressed on endothelial cells, particularly HEV. The weak binding of CD62L to its ligand mediates a weak adhesion to the vessel wall, which, combined with the force of blood flow, results in rolling of the T cell along the endothelium. The increased cell contact assists the interaction of a second adhesion molecule on lymphocytes, the integrin LFA-1 ($CD11a/CD18$) with its ligands, ICAM-1 ($CD54$), and ICAM-2 ($CD102$). This results in the arrest of rolling and firm attachment. Migration into the extracellular matrix of tissues may involve additional lymphocyte cell surface molecules such as the hyaluronate receptor ($CD44$) or the integrin $\alpha 4\beta 7$ ($CD49d/\beta 7$) that binds the mucosal addressin cell adhesion molecule-1 (MAdCAM-1) on endothelium of Peyer's patches and other endothelial cells.

Other cytokines known as *chemokines* may contribute to lymphocyte homing. Chemokines are structurally and functionally related to proteins bearing an affinity for heparan sulfate proteoglycan and promote migration of various cell types.²¹ The chemokines RANTES, MIP-1 α , MIP-1 β , MCP-1, and IL-8 are produced by a number of cell types including endothelium, activated T cells, and monocytes and are present at inflammatory sites such as rheumatoid synovium (see Chapter 70).

Once mature T cells have reached the peripheral lymphoid tissues of lymph node and spleen, they undergo a low level of turnover known as *homeostatic proliferation in response to self-peptide/MHC complexes*, $IL-7$, and $IL-15$.²² This serves to maintain the number of peripheral T cells, which can become accelerated in states of lymphopenia such as following chemotherapy or irradiation.²³ Because homeostatic proliferation is driven by self-MHC/peptides, its

Figure 13-4 T cell antigen receptor (TCR) signal pathways. Schema showing the principal signal pathways resulting from TCR activation and how they impinge on the regulatory region of the interleukin-2 (IL-2) gene. See text for details.

acceleration could precipitate an autoimmune syndrome. In this regard, it is of interest that one of the standard models of autoimmunity is day 3 thymectomy, which results in lymphopenia,²⁴ NOD diabetic mice have chronic lymphopenia that contributes to their diabetes,²⁵ and evidence of augmented homeostatic proliferation has been suggested to occur in rheumatoid arthritis.²⁶

ACTIVATION OF T CELLS

T cell activation initiates intracellular signaling cascades that ultimately result in proliferation, effector function, or death, depending on the developmental stage of the cell. To guard against premature or excessive activation, T cells have a requirement of two independent signals for full activation. Signal 1 is an antigen-specific signal provided by the binding of the TCR to antigenic peptide complexed with MHC. Signal 2 is mediated by either cytokines or the engagement of co-stimulatory molecules such as B7.1 (CD80) and B7.2 (CD86) on the antigen-presenting cell (APC). Receiving only signal 1 without co-stimulation results in T cell unresponsiveness or anergy.

TCR and Tyrosine Kinases

TCR $\alpha\beta$ and $\gamma\delta$ have short cytoplasmic domains and by themselves are unable to transduce signals. The molecules of the noncovalently associated CD3 complex couple the TCR to intracellular signaling machinery (Figure 13-4). The CD3 complex contains nonpolymorphic members known as CD3 ϵ , CD3 γ , CD3 δ , and ζ and η chains that are alternatively spliced forms of the same gene and are not genetically linked to the CD3 complex. Although the functional stoichiometry of the TCR complex is not completely

defined, current data indicate that each TCR heterodimer is associated with three dimers: CD3 $\epsilon\gamma$, CD3 $\epsilon\delta$, and $\zeta\zeta$ or ζ . CD3 ϵ , γ , and δ have an immunoglobulin-like extracellular domain, a transmembrane region, and a modest cytoplasmic domain, whereas ζ contains a longer cytoplasmic tail. The transmembrane domains of ζ and the CD3 chains contain a negatively charged residue that interacts with positively charged amino acids in the transmembrane domain of the TCR.

None of the proteins in the TCR complex has intrinsic enzymatic activity. Instead, the cytoplasmic domains of the invariant CD3 chains contain conserved activation domains that are required for coupling the TCR to intracellular signaling molecules. These immunoreceptor tyrosine-based activation motifs (ITAMS) contain a minimal functional consensus sequence of paired tyrosines (Y) and leucines (L): (D/E)XXYXXL(X)₆₋₈YXXL. ITAMs are substrates for cytoplasmic protein tyrosine kinases (PTKs), and upon phosphorylation they recruit additional molecules to the TCR complex.²⁷ Each ζ chain contains three ITAMs, whereas there is one in each of the CD3 ϵ , γ , and δ chains. Thus each TCR complex can contain as many as 10 ITAMs.

Activation of PTKs is one of the earliest signaling events following TCR stimulation. Four families of PTKs are known to be involved in TCR signaling: Src, Csk, Tec, and Syk. The Src family members Lck and Fyn^T have a central role in TCR signaling and are expressed exclusively in lymphoid cells. Src PTKs contain multiple structural domains including (1) N-terminal myristylation and palmitoylation sites, which allow association with the plasma membrane; (2) a Src homology (SH) 3 domain, which associates with proline-rich sequences; (3) an SH2 domain that binds phosphotyrosine-containing proteins; and (4) a

carboxy-terminal negative regulatory site. Their catalytic activity is regulated by the balance between the actions of kinases and phosphatases. Activity is repressed by phosphorylation of a conserved carboxy-terminal tyrosine, and dephosphorylation by the phosphatase CD45 is critical for the initiation of TCR-mediated signal transduction. In addition, autophosphorylation of other tyrosines within the kinase domain enhances catalytic activity. Lck is physically and functionally associated with CD4 and CD8. Fifty percent to 90% of total Lck molecules are associated with CD4 and 10% to 25% with CD8. CD4 and CD8 physically associate with the TCR/CD3 complex during antigen stimulation as a result of their interaction with MHC class II and class I molecules and thus enhance TCR-mediated signals by recruiting Lck to the TCR complex. Lck phosphorylates the CD3 chains, TCR ζ , ZAP-70, phospholipase C- γ 1 (PLC- γ 1), Vav, and Shc. Fyn binds TCR ζ and CD3 ϵ and, although its substrates are less well defined, T cells lacking Fyn have diminished response to TCR signals.^{28,29} Vitamin D, whose deficiency is linked to various autoimmune disorders, strongly upregulates PLC- γ 1 following TCR activation and enhances signaling efficiency.³⁰ In addition, the SH2 and SH3 domains of Src PTKs can mediate their association with, respectively, phosphotyrosine- and proline-containing molecules.

Somewhat less is known about the Csk and Tec PTKs. Csk negatively regulates TCR signaling by phosphorylating the carboxy-terminal tyrosine of Lck and Fyn. Dephosphorylation of this negative regulatory tyrosine is mediated by the transmembrane tyrosine phosphatase CD45. CD45 activity is essential for TCR signaling as CD45-deficient T cells fail to activate by TCR stimulation. The Tec family member Itk is preferentially expressed in T cells. T cells from Itk-deficient mice have diminished response to TCR stimulation. The mechanism by which Itk regulates TCR signaling has not been determined, although recent studies have shown that Itk is an important component of the pathway leading to increased intracellular Ca²⁺.

Phosphorylation of the ITAM motifs on the CD3 complex recruits the Syk kinase family member ZAP-70 by its tandem SH2 domains. ZAP-70 is expressed exclusively in T cells and is required for TCR signaling. Like the Src family PTKs, ZAP-70 is positively and negatively regulated by its phosphorylation. Phosphorylation of tyrosine 493 by Lck activates ZAP-70 kinase activity. In murine thymocytes and ex vivo T cells, inactive non-phosphorylated ZAP-70 is constitutively associated with the basally phosphorylated TCR ζ chain via the SH2 domain of ZAP-70.³¹ TCR stimulation is required for ZAP-70 phosphorylation and activation. The recruitment of ZAP-70 to the TCR complex assists the tyrosine phosphorylation and activation of ZAP-70 by Lck. Loss-of-function hypomorphic alleles of ZAP-70 result in reduced TCR signaling and a propensity for autoimmune phenomena such as rheumatoid factor production.³²

Adaptor Proteins

Phosphorylation of tyrosine residues in ITAMs and PTKs following TCR stimulation creates docking sites for adaptor proteins. Adaptor proteins contain no known enzymatic or transcriptional activities but mediate protein-protein

interactions or protein-lipid interactions. They function to bring proteins in proximity to their substrates and regulators, as well as sequester signaling molecules to specific subcellular locations. The protein complexes formed can function as either positive or negative regulators of TCR signaling depending on the molecules they contain.

Two critical adaptor proteins for linking proximal and distal TCR signaling events are SH2-domain-containing leukocyte protein of 76 kDa (SLP-76) and Linker for activation of T cells (LAT) (see Figure 13-4). Loss of these adaptor proteins has profound consequences for T cell development. Mice deficient for LAT or SLP-76 manifest a block in T cell development at the CD4⁻CD25⁺CD44⁺ stage. LAT is constitutively localized to lipid rafts and, following TCR stimulation, is phosphorylated on tyrosine residues by ZAP-70. Phosphorylated LAT then recruits SH2-domain-containing proteins including PLC γ 1, the p85 subunit of phosphoinositide-3 kinase, IL-2 inducible kinase (Itk), and the adaptors Grb2 and Gads. Because the SH3 domain of Gads is constitutively associated with SLP-76, this brings SLP-76 to the complex where it is phosphorylated by ZAP-70. SLP-76 contains three protein binding motifs: tyrosine phosphorylation sites, a proline-rich region, and an SH2 domain. The N terminus of SLP-76 contains tyrosine residues that associate with the SH2 domains of Vav, the adaptor Nck, and Itk. Vav is a 95-kD protein that acts as a guanine nucleotide exchange factor for the Rho/Rac/cdc42 family of small G proteins. The complex of LAT, SLP-76/Gads, PLC γ 1, and associated molecules results in the full activation of PLC γ 1 and activation of Ras/Rho GTPases and the actin cytoskeleton.

In addition to acting as positive regulators for TCR signaling, adaptors can also mediate negative regulation. As described previously, the activity of the Src family kinases is regulated by the interaction of kinases (Csk) and phosphatases (CD45) specific for inhibitory C-terminal phosphotyrosine. This is determined by the subcellular localization of these regulatory molecules. A second mechanism by which adaptor proteins can negatively regulate TCR stability is through regulation of protein stability. c-Cbl and Cbl-b are members of a conserved family of proteins that contains a highly conserved N-terminal region containing a tyrosine kinase-binding and RING-finger domains. c-Cbl RING finger domain binds the E2 ubiquitin-conjugating enzymes. Active E2 enzymes are brought into proximity with tyrosine kinase-binding proteins resulting in their ubiquitination and degradation by the proteasome complex. Syk and ZAP-70 associate with c-Cbl while Vav, ZAP-70, LCK PLC γ 1, and the p85 subunit of PI3K associate with Cbl-b.

Downstream Transcription Factors

The previously mentioned signaling events couple TCR stimulation to downstream pathways that culminate in changes in gene transcription that are required for proliferation and effector function (see Figure 13-4). One of the best characterized genes induced following T cell activation is the T cell growth factor IL-2. Transcription of the IL-2 gene is regulated in part by the transcription factors AP-1, nuclear factor of activated T cells (NFAT), and nuclear factor κ B (NF κ B), all of which are activated following TCR

stimulation. Proximal signaling events lead to the activation of Ras and PLC γ .³³ Ras initiates a cascade of kinases including Raf-1, MEK, and the MAP kinase ERK, which leads to the production of the transcription factor Fos. Ligation of the co-stimulatory molecule CD28 results in the activation of another member of the MAP kinase family, c-Jun N-terminal kinase (JNK), and phosphorylation of the transcription factor c-Jun. c-Jun and Fos associate to form AP-1. PLC γ hydrolyzes membrane inositol phospholipids to generate phosphoinositide second messengers including inositol 1,4,5 triphosphate (IP3) and diacylglycerol. IP3 stimulates the mobilization of calcium from intracellular stores. Diacylglycerol activates protein kinase C (especially PCK θ in T cells) and, along with CARMA, connects with the NF κ B pathway.³³

Increased intracellular calcium is central to many forms of cellular activation. Calcium activates the calcium/calmodulin-dependent serine phosphatase calcineurin, which dephosphorylates NFAT.³⁴ Dephosphorylated NFAT translocates to the nucleus and, together with AP-1, forms a trimolecular transcription factor for the IL-2 gene. The immunosuppressive agents cyclosporin-A and FK-506 specifically inhibit the calcium-dependent activation of calcineurin, thereby blocking activation of NFAT and the transcription of NFAT-dependent cytokines such as IL-2, IL-3, IL-4, and GM-CSF. Recently, it has been appreciated that differences in the amplitude and duration of calcium signals mediate different functional outcomes. Although high spikes of calcium are easily measured in lymphocytes during the first 10 minutes following antigen stimulation, sustained low-level calcium spikes over a few hours are necessary for full activation. These latter, more subtle calcium fluxes appear to be controlled by cyclic-ADP-ribose and ryanodine receptors.³⁵ Selective inhibitors exist for these molecules, opening the potential for new specific blockers of T cell activation.

A surprising discovery was the observation that caspase activity, particularly of caspase-8, is required to initiate T cell proliferation and activation of NF κ B.^{36,37} Previously the role of caspases had been confined to apoptosis. However, it is now appreciated that following TCR ligation, caspase-8 is activated and forms a complex that includes the NF κ B adaptor proteins CARMA1, Bcl-10, and MALT1.³⁸

Co-stimulation

Signal 2 serves to augment the activation of PI3 kinase and AKT, which augments not only growth factor production but also survival and general metabolic signals. The prototype co-stimulatory signal is CD28 interacting with B7-1 (CD80) or B7-2 (CD86). CD28 is a disulfide-linked homodimer constitutively expressed on the surface of T cells. Virtually all murine T cells express CD28, whereas in human T cells, nearly all CD4⁺ and 50% of CD8⁺ cells express CD28. The CD28⁻ subset of T cells appears to represent a population that has undergone chronic activation and can manifest suppressive activity. Increased levels of CD28⁻ T cells have been reported in several inflammatory and infectious conditions including granulomatosis with polyangiitis (formerly Wegener's granulomatosis), rheumatoid arthritis, cytomegalovirus, and mononucleosis.³⁹⁻⁴¹ The cytoplasmic domain of CD28 has no known enzymatic activity but does

contain two SH3 and one SH2 binding sites. CD28 interacts with PI3 kinase and GRB2 and promotes JNK activation, as noted earlier. CD28 ligation alone does not transmit a proliferative response to T cells, but in conjunction with TCR engagement augments IL-2 production at the level of both transcription and translation. It also increases the production of other cytokines including IL-4, IL-5, IL-13, IFN- γ , and TNE, as well as the chemokines IL-8 and RANTES.

The ligands for CD28, CD80 (B7-1), and CD86 (B7-2) are expressed in a restricted distribution on B cells, dendritic cells, monocytes, and activated T cells. CD80 and CD86 have similar structures but share only 25% amino acid homology. They each contain rather short cytoplasmic tails that may signal directly and bind to CD28 with different avidities.

Immunologic Synapse

Antigen-specific interaction between the T cell and APC results in the formation of a specialized contact region called the *immunologic synapse* or *supramolecular activation cluster* (SMAC)⁴² (Figure 13-5). Synapse formation is an active, dynamic process that requires specific antigen to drive synapse formation; TCR:MHC interaction alone is not sufficient. The synapse also overcomes the obstacles to close T cell/APC contact mediated by short molecules (e.g., TCR, MHC, CD4, CD8) caused by interactions of tall molecules (ICAM-1, LFA-1, CD45). Two stages of assembly have been described. During the nascent stage, cell adhesion molecules such as ICAM-1 on APC and LFA-1 on T cells make contact in a central zone, surrounded by an annulus of close contact between MHC and TCR.⁴² Within minutes the engaged TCR migrates to the central area, resulting in a mature synapse in which the initial relationships are reversed—the central area (CSMAC) now contains TCR, CD2, CD28, and CD4 and is enriched for Lck, Fyn, and PKC θ .⁴³ Surrounding the central domain is a peripheral ring (pSMAC) that contains, CD45, LFA-1, and associated talin. T cell activation leads to compartmentalization of activated TCR and TCR signaling molecules to plasma membrane microdomains called “rafts.”⁴⁴ Rafts are composed primarily of glycosphingolipids and cholesterol and are enriched in signaling molecules, actin, and actin-binding proteins.⁴⁵ Src family kinases, Ras-like G proteins, LAT, and phosphatidylinositol-anchored membrane proteins have all been shown to localize to raft domains.

Full T cell activation requires engagement of a minimum of about 100 to 200 MHC/peptide molecules on an APC, which can serially stimulate 2000 to 8000 TCR. It has been estimated that naïve T cells also require a sustained signal for 15 to 20 hours to commit to proliferation.⁴⁶ T cells face a number of obstacles to achieving full activation including the small physical size of the TCR and MHC molecules compared with other cell surface molecules, the low affinity of TCR for MHC/peptide complex, and the low number of MHC molecules present on the APC that contain the antigenic peptide.⁴⁷ The immunologic synapse may provide the mechanism for overcoming these barriers and achieving the duration of TCR stimulation necessary to commit the cell to proliferation.⁴² The spatial organization of the synapse juxtaposes the membranes of the APC and T cell, assisting

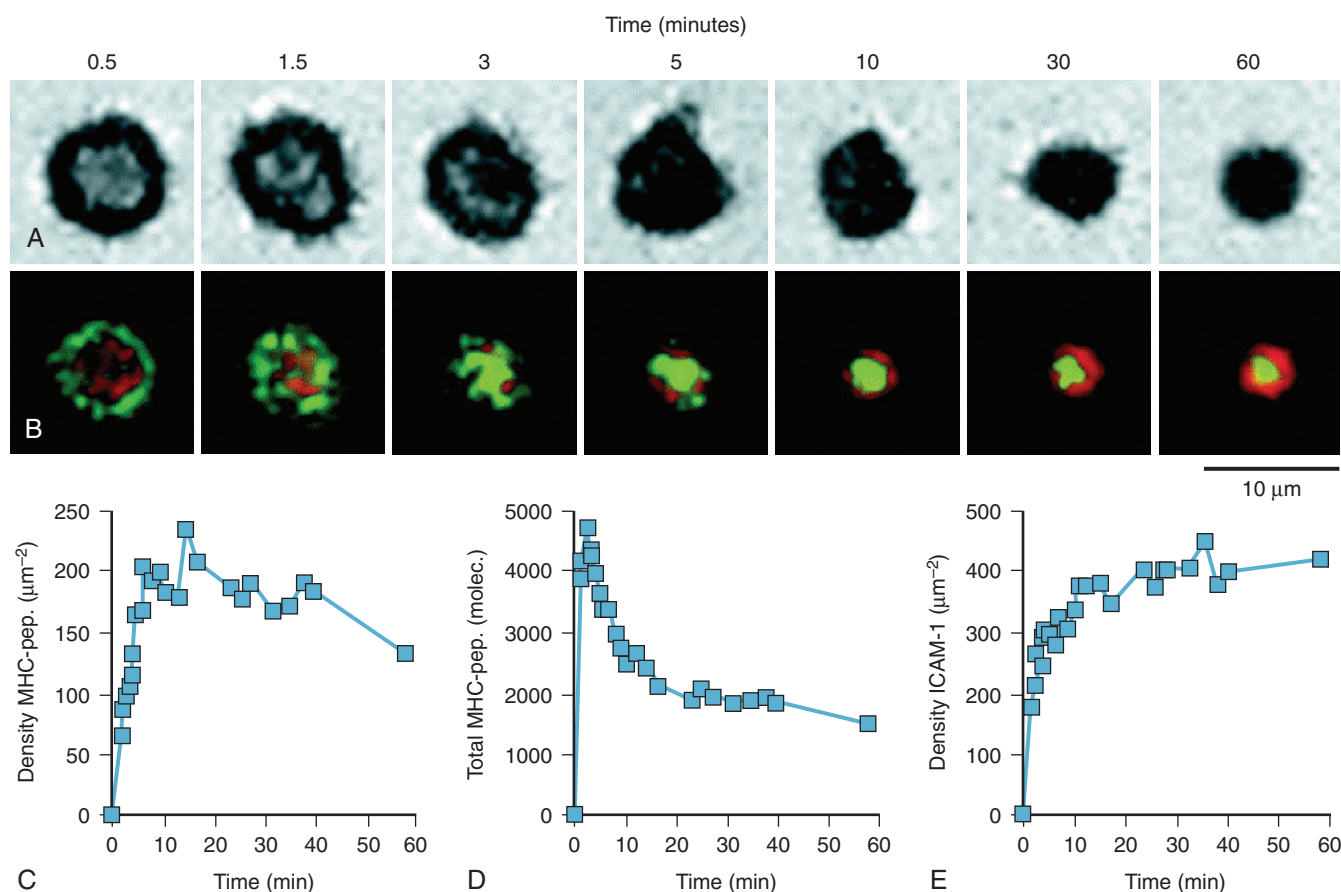

Figure 13-5 Formation of the immunologic synapse. **A**, Contact areas of T cells shown over the time points indicated as dark gray against a light background. **B**, Images containing Oregon green E^k-antigen (mouse cytochrome peptide 88-103) and Cy5 ICAM-1. **C**, Density of accumulated E^k-MCC88-103. **D**, Total accumulated E^k-MCC88-103. **E**, Density of accumulated ICAM-1. (From Grakoui S, Bromley K, Sumen C, et al: *The immunological synapse: a molecular machine controlling T cell activation*. Science 285:221–227, 1999.)

the interaction of the TCR and MHC/peptide complex. The available MHC/peptide complexes and TCR are concentrated at the site of contact via actin cytoskeleton-mediated transport. The multistep process of mature synapse formation may also enable the T cell to discriminate between the potential antigen-containing MHC/peptide complexes it encounters on the APC cell surface. It has been shown that co-stimulatory signals may contribute to synapse formation by initiating the transport of membrane rafts containing the kinases and adaptor molecules required for TCR signaling to the site of contact.⁴⁸

Although it has been appreciated for some time that chronic infection can lead to an unresponsive state or “exhausted” T cells, the molecular explanation for this was unknown. More recently it was observed that chronically activated CD8⁺ T cells contain more mRNA encoding the inhibitory receptor PD1 (programmed death 1) than acutely activated CD8⁺ T cells.⁴⁹ In parallel, one of the ligands for PD-1, PDL1, was highly expressed by chronically infected splenocytes. Treatment of mice with a blocking antibody to PDL1 caused virus-specific CD8⁺ T cells to undergo marked expansion. The fact that many tumors also express PDL1 enhances the interest in reversing suppression of immune responses during infection and tumorigenesis. The fact that PD-1-deficient mice develop spontaneous autoimmunity

enhances interest in manipulating PD-1 for therapeutic purposes.⁵⁰

Tolerance and Control of Autoreactive T Cells

The immune system is constantly confronted by the problem of how to ensure that T cells are activated only under conditions where there is a true need for a response to a foreign pathogen and not merely a self-component. As with many biologic filters, thymic negative selection is not 100% efficient and not all self-reactive T cells are eliminated. Hence a variety of fail-safe mechanisms are engaged to suppress the ability of these errant T cells to undergo premature clonal expansion. This is partly regulated by the requirement for two distinct signals from separate molecules to be coordinately triggered in order for T cell activation and proliferation to proceed. If only one of the signals is received, the T cell will not proliferate and will actually enter a nonresponsive state known as tolerance or anergy.

The anergy that results from the absence of a CD28 co-stimulatory signal manifests at a signal level by a failure to fully couple the TCR signal to the Ras/MAP kinase pathway and consequent AP-1 transcriptional activity. An additional method of provoking an incomplete TCR signal

and unresponsiveness is to make amino acid substitutions in the recognized peptide antigen. These so-called altered peptide ligands (APLs) cause a suboptimal phosphorylation of TCR ζ and consequent inefficient recruitment of ZAP-70.

Following the discovery of CD28 as a co-stimulatory molecule, a related structure known as CTLA-4 was found to also bind to CD80 and CD86 with 20-fold higher affinity than CD28. Unlike CD28, CTLA-4 is expressed only transiently following T cell activation and confers an inhibitory signal for T cell proliferation.⁵¹ In this capacity, CTLA-4 functions to limit T cell clonal expansion induced by CD28. The consequences of the loss of this negative regulation are striking. The genetic deletion of the *CTLA-4* gene in mice results in enormous uncontrolled T cell expansion and an autoimmune diathesis.⁵²

Chronic exposure to certain inflammatory cytokines, most notably TNF, can also induce anergy. It has been appreciated for some time that T cells from rheumatoid synovium manifest profound deficiencies of proliferation and cytokine production.⁵³ Since TNF is one of the major cytokines detectable in rheumatoid synovial fluid, it was soon appreciated that chronic exposure of T cell clones to TNF for 10 to 12 days suppressed proliferative and cytokine responses to antigen by as much as 70%.⁵⁴ Furthermore, a single administration of anti-TNF receptor monoclonal antibody to patients with rheumatoid arthritis rapidly restored the response of peripheral T cells to mitogens and recall antigens.⁵⁴ Similar observations have been made in TCR transgenic mice following TNF exposure.⁵⁵ The observation that chronic TNF exposure inhibited calcium responses following TCR ligation⁵⁵ supports the view that TNF may uncouple TCR signaling. Conceivably other members of the TNF family may invoke similar T cell anergy.

An additional negative regulator for T cells is the B lymphocyte-induced maturation protein 1 (Blimp-1), previously felt to be expressed only in B lymphocytes. Blimp-1-deficient mice manifest augmented levels of peripheral effector T cells and develop severe colitis as early as 6 weeks of age.⁵⁶ Blimp-1 messenger RNA expression increases with TCR stimulation, and Blimp-1-deficient T cells proliferated more and produced more IL-2 and IFN- γ following activation.⁵⁶

Another layer of regulation occurs via a phenotypically defined subpopulation of CD4⁺CD25⁺ FoxP3⁺ regulatory T cells (Treg) that has the ability to inhibit antigen-induced proliferation.⁵⁷ This subset is expressed in the periphery at a low frequency and appears to be at least partly thymic dependent. The latter point may be of interest because it suggests that the absence of regulatory T cells following day 3 thymectomy may be involved with the subsequent development of autoimmune disease in these animals.⁵⁸ Indeed, diminished levels of CD4⁺CD25⁺ FoxP3⁺ regulatory T cells have been observed in other autoimmune syndromes and the transfer of Treg to autoimmune mice has shown some alleviation of symptoms. The production of TGF- β and IL-10 appear to be critical to the suppressive activity of Treg.⁵⁹ This is an active area of research because of the potential therapeutic implications for autoimmune diseases and their possible role in generating IL-17-producing CD4⁺ T cells (Th17, see later).⁶⁰ In this regard, recent studies to

treat type 1 diabetes by increasing Treg number and function using anti-CD3 antibody or IL-2 are promising.⁶¹

SUBSETS AND FUNCTION OF PERIPHERAL T CELLS

CD4 Helper and CD8 Cytolytic T Cells

$\alpha\beta$ T cells can be subdivided into two main subsets based on their recognition of peptides presented by MHC class I or class II molecules and their respective expression of CD8 or CD4. CD4⁺ and CD8⁺ T cells have different functions and recognize antigens derived from different cellular compartments. The peptides presented by MHC class I molecules are produced by the proteasome⁶² and can be derived from either self-proteins or intracellular foreign proteins as might occur during viral infection. MHC class II-bound peptides are derived largely from extracellular infectious agents or self-cell surface proteins that have been engulfed and degraded in the lysosomal complex.

CD4⁺ T cells express a variety of cytokines and cell surface molecules that are important to B cell proliferation and immunoglobulin production and CD8⁺ T cell function. Following antigen stimulation, CD4⁺ T cells differentiate into different classes of effector T cells based on their cytokine profiles including T helper 1 (Th1), Th2, Th17, Tfh cells (described later), and Treg cells (described earlier) (Figure 13-6). The CD4 molecule is structurally related to immunoglobulins and has an affinity for nonpolymorphic residues on the MHC class II molecule. In this capacity CD4 presumably increases the efficiency with which CD4⁺ T cells recognize antigen in the context of MHC class II molecules, whose expression is restricted to B cells, macrophages, dendritic cells, and a few other tissues during states of inflammation. In addition, the cytoplasmic tail of CD4 binds to Lck and promotes signaling by the TCR, as described earlier. However, ligation of CD4 before engagement of the TCR renders the T cell susceptible to apoptosis on subsequent engagement of the TCR.⁶³ This is clinically important in human immunodeficiency virus (HIV) infections in which the gp120 molecule of HIV binds to CD4 and primes the T cell to undergo cell death when later triggered by the TCR. Accelerated apoptosis of CD4⁺ T cells has been demonstrated in acquired immunodeficiency syndrome (AIDS) patients.⁶⁴

CD8⁺ T cells are efficient killers of pathogen-infected cells. Given the ubiquitous expression of MHC class I molecules, mature cytolytic T cells (CTLs) can recognize viral infections in a wide array of cells, in distinction to the more restricted distribution of class II molecules. CTLs lyse target cells through the production of perforin, which induces holes in cell membranes, and the expression of Fas-ligand and TNF, which induce apoptosis. In this capacity CTLs kill virally infected target cells in an attempt to restrict the spread of infection. Similar to CD4, CD8 manifests an affinity for MHC class I molecules, enhances the signaling of CTL, and also binds Lck by its cytoplasmic tail.

T Cells in the Innate Immune Response

In addition to the broad array of antigens recognized by $\alpha\beta$ T cells, there is growing appreciation that the immune

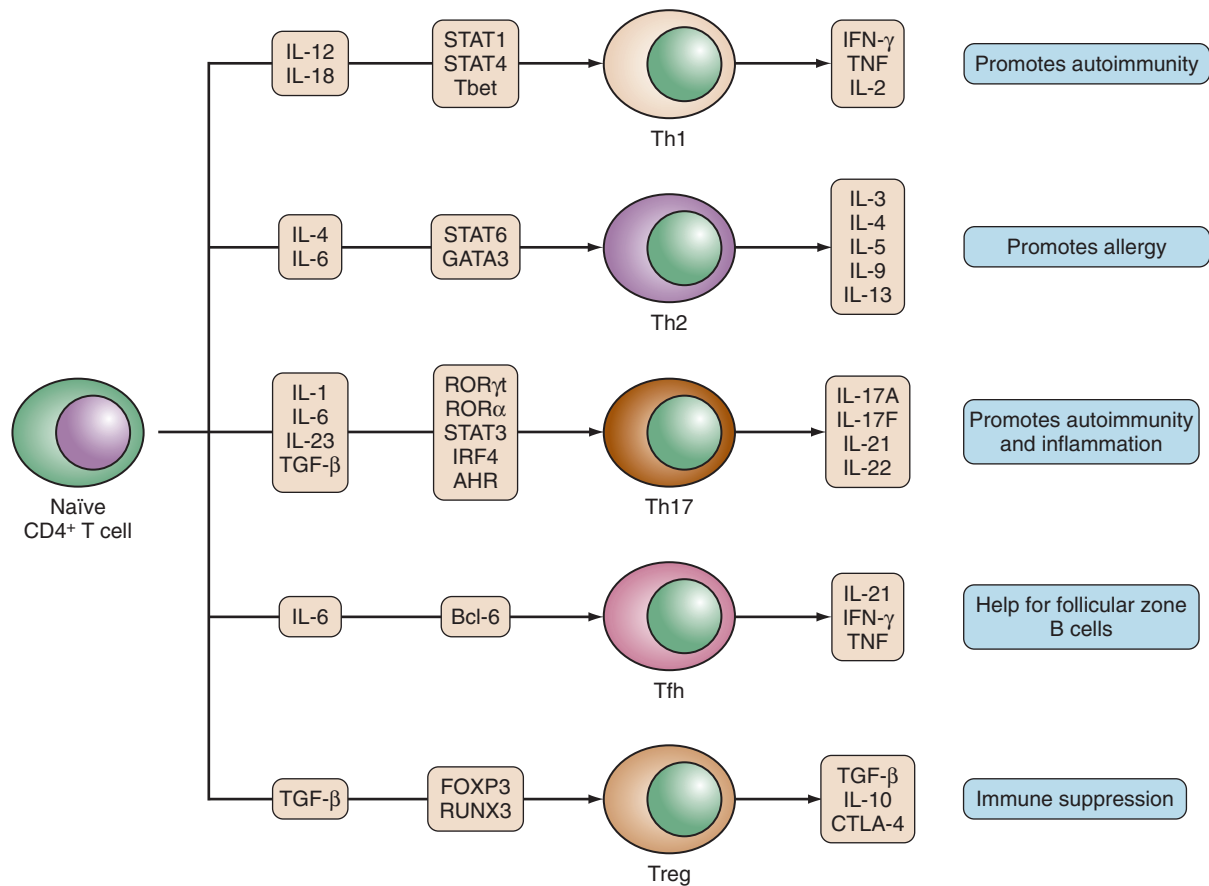

Figure 13-6 T helper subsets. Naïve CD4 T cells can be polarized into producing particular patterns of cytokines depending on the cytokine environment in which they develop, as well as the expression of certain transcription factors. AHR, aryl hydroxylase receptor.

system also contains small subpopulations of T cells that may be specialized to recognize conserved structures that are either uniquely expressed by prokaryotic pathogens or on stressed host cells. These are discussed in detail in Chapter 18. Such common antigenic motifs include bacterial lipoproteins recognized by Toll-like receptor (TLR)-2 and TLR-4, double-stranded RNA from RNA viruses that bind TLR-3, and methylated cytosine residues in bacterial CpG sequences, or anti-DNA/DNA complexes that bind to TLR-9.⁶⁵ TLRs expressed by APC can trigger the release of cytokines and co-stimulatory molecules for T cells. Another family of molecules that likely binds bacterial components is CD1. CD1 structurally resembles MHC class I but contains a deeper and more hydrophobic binding pocket that can accommodate certain lipopeptides and glycolipids. By using such molecular strategies to focus on common and nonpolymorphic molecules, the immune response can respond quickly during the early phase of infections. This response is part of the innate immune response. Although it may represent the remnants of an evolutionarily more primitive immune response, it nevertheless provides a vital early defense system. Among T cells this function is provided by $\gamma\delta$ and natural killer (NK) T cells.

$\gamma\delta$ T Cells

$\gamma\delta$ T cells were identified following serendipitous discovery of rearranged genes while searching for the TCR α -chain

gene, rather than a preexisting knowledge of their presence and biologic function.⁶⁶ Structurally, the γ -chain locus contains at least 14 V γ region genes, of which six are pseudogenes, each capable of rearranging to any of 5 J γ regions and two C γ regions. The δ -chain genes are nested within the α -chain gene locus between V α and J α . There are about six V δ regions, two D δ and two J δ regions, and a single C δ gene. Transcription of rearranged γ and δ genes begins before $\alpha\beta$ genes and is apparent on days 15 to 17 of mouse thymus development, after which it declines in the adult thymus. In addition to the ordered appearance of TCR- $\gamma\delta$ before TCR- $\alpha\beta$, there is also a highly ordered expression of γ and δ V-region genes during early thymic development. This results in successive waves of oligoclonal $\gamma\delta$ T cells migrating to the periphery. The reason for this remarkable regimentation remains unclear.

$\gamma\delta$ T cells manifest a number of differences from $\alpha\beta$ T cells. $\gamma\delta$ T cells are often anatomically sequestered to epithelial barriers or sites of inflammation and frequently manifest cytotoxicity toward a broad array of targets.⁶⁷ In contrast to $\alpha\beta$ T cells, $\gamma\delta$ cells can respond to antigen directly, without evidence of MHC restriction,⁶⁸ or conversely, react to MHC molecules without peptide.⁶⁹

Human $\gamma\delta$ T cell clones, particularly those expressing the V δ 2 gene, and derived from peripheral blood of normal individuals, frequently react to nonprotein components of mycobacteria.⁷⁰ These have been identified as nucleotide triphosphates,⁷¹ prenyl pyrophosphate,⁷² and alkylamines.⁷³

These molecules are, respectively, subunits in DNA and RNA, substrates in lipid metabolism for the synthesis of farnesyl pyrophosphate, and products of pathogenic organisms. In mammalian cells, farnesyl addition is a critical modification for targeting certain signaling molecules to the cell membrane such as Ras. This process appears critical to cell transformation. These phosphate-containing nonpeptides can be found in both microbial and mammalian cells. This suggests that $\gamma\delta$ cells may recognize a class of antigens shared by a number of pathogens, as well as by damaged or transformed mammalian cells, and may provide insight into the role of $\gamma\delta$ cells in infection and their accumulation at sites of inflammation. Another subpopulation of $\gamma\delta$ T cells expressing the V γ 1 gene is typically found in the intestine and in inflamed synovial fluid and reacts to the MHC class I-like molecules known as MICA and MICB.⁷⁴ Unlike classical MHC class I molecules that are expressed ubiquitously and continuously, MICA and MICB expression appears to be restricted to gut epithelium and occurs only during times of stress, similar to that of a heat shock response.

The contribution of $\gamma\delta$ T cells to defense against infection has been examined in mice using a number of pathogens including *Listeria*, *Leishmania*, *Mycobacterium*, *Plasmodium*, and *Salmonella*. All of these studies have shown a moderately protective role for $\gamma\delta$ T cells. The cumulative evidence suggests that $\gamma\delta$ T cells may not react directly to components of microorganisms, but rather indirectly via the ability of microbial products to stimulate the innate immune response. An example is the $\gamma\delta$ T cells in synovial fluid from Lyme arthritis, which are activated by *Borrelia burgdorferi* lipidated hexapeptides of the outer surface proteins that stimulate TLR2.

$\gamma\delta$ T cells accumulate at inflammatory sites in autoimmune disorders such as rheumatoid arthritis,⁷⁵ celiac disease,⁷⁶ and sarcoidosis.⁷⁷ The reason for this remains an enigma. However, there is evidence that $\gamma\delta$ cells can be highly cytolytic toward a variety of tissues including CD4⁺ T cells,⁷⁸ in part due to their high and sustained expression of surface Fas-ligand.⁷⁹ Their presence can strongly bias the cytokine profiles of the infiltrating CD4⁺ cells, in some instances toward Th1 profiles,⁸⁰ and in others toward Th2.⁸¹

Natural Killer T Cells

A minor subpopulation of T cells bearing the NK determinant manifest a curiously restricted TCR repertoire. NK T cells are found within the CD4⁺ and CD4⁻8⁻ T cell subsets and, in both mouse and human, express a limited number of TCR-V β chains and an invariant α -chain (V α 14 in mice and V α 24 in humans).⁸² Furthermore, most NK T cells are restricted in their response to a monomorphic MHC class I-like molecule, CD1d. Crystallographic analysis of CD1d has shown that it contains a deeper groove than traditional MHC molecules and is highly hydrophobic, conferring a preference for binding lipid moieties. Originally, the sea sponge sphingolipid, α -galactosylceramide was the only known CD1d ligand. Now both endogenous and bacterial (*Sphingomonas* and *Borrelia burgdorferi*) sources of CD1d-binding sphingolipids have been identified.^{83,84} This may represent another type of innate T cell response whereby bacterial lipids or lipopeptides may be presented to NK T cells to provoke a rapid early immune response.

The potential importance of NK T cells in autoimmune disease stems from their rapid production of high levels of certain cytokines, particularly IL-4 and IFN- γ .⁸² In this capacity, the IL-4 response may be important for modulating inflammatory responses dominated by Th1 infiltrates. This has been noted in the nonobese diabetic (NOD) mouse model of diabetes, which has reduced levels of NK T cells.⁸⁵ Adoptive transfer of NK T cells into NOD mice blocks the onset of diabetes.⁸⁶ A study extended this observation to human type 1 diabetes. The NK T cells of diabetic individuals produced more IFN- γ and less IL-4 than their unaffected siblings.⁸⁷ NKT cells have also been reported to be the predominant CD4⁺ T cell in the airways of asthma patients.⁸⁸ Thus this minor population of T cells may play a pivotal role in early innate responses to certain infections and also in the regulation of inflammatory sites.

Naïve versus Memory T Cells

CD4⁺ and CD8⁺ T cells emigrate from the thymus bearing a naïve phenotype. Naïve T cells produce IL-2 but only low levels of other cytokines and as such provide little B cell help. Naïve T cells express high levels of Bcl-2 and can survive for extended periods without antigen but require the presence of MHC molecules. Naïve T cells circulate from the blood to lymphoid tissues of the spleen and lymph nodes, where antigen, APC, T cells, and B cells are concentrated. Particularly important in this environment as APC are dendritic cells, which can migrate from other areas of the body such as the skin and are highly efficient at processing and presenting antigen to T cells (see Chapter 10). Dendritic cells express high and constitutive levels of MHC class II and co-stimulatory molecules B7-1 (CD80) and B7-2 (CD86), which are critical to promoting proliferation of naïve T cells. In this capacity dendritic cells are particularly adept at promoting clonal expansion of antigen-specific T cells. The development of antigen peptide/MHC tetramer technology has led to direct quantitation of antigen-specific CD8 T cells using flow cytometry. Viral-specific CD8 T cells have an incredible ability to expand following infection, from levels that are undetectable to nearly 50% of the CD8 population, representing a nearly 1000-fold increase in only a few days.⁸⁹

During the process of clonal expansion of naïve T cells and their differentiation into effector and eventually memory T cells, up to 100 genes are induced. These are manifest primarily as increased expression of certain surface molecules involved with cell adhesion and migration (CD44, ICAM-1, LFA-1, α 4 β 1 and α 4 β 7 integrins, the chemokine receptor CXCR3); activation (CD45 change from high-molecular-weight CD45RA to lower molecular weight CD45RO isotype); cytokine production (increased production of IFN- γ , IL-3, IL-4, and IL-5); and death receptors (e.g., Fas/CD95) (Table 13-1). More transiently induced are CD69, the survival factor Bcl-xL, and the high affinity growth factor IL-2 receptor α -chain (CD25). Survival of effector T cells to the memory stage is partly dependent on the cytokines IL-7 and IL-15.⁹⁰

The concept of immune memory has existed since the first successful vaccinations by Jenner for smallpox. A useful memory T cell marker in the murine system is CD44, the hyaluronate receptor. Surface CD44 is low on mature

Table 13-1 Surface Markers on Naïve and Memory T Cells

Molecule	Other Designation	Molecular Weight (kD)	Characteristic	Expression	
				Memory	Naïve
CD58	LFA-3	45-66	Ligand for CD2	++	+
CD2	T11	50	Alternative activation pathway	+++	++
CD11a/CD18	LFA-1	180-195	Receptor for ICAM-1, ICAM-2, ICAM-3	+++	++
CD29		130	β chain of $\beta 1$ (VLA) integrins	++++	+
CD45RO		220	Isoform of CD45	++++	—
CD45RA		80-95	Isoform of CD45	—	++++
CD44	Pgp-1	90	Receptor for hyaluronic acid	+++	++
CD54	ICAM-1	120	Counterreceptor for LFA-1	+	—
CD26		40	Dipeptidyl peptidase IV	+	—
CD7		Multichain complex	T cell lineage marker	+/-	++
CD3			Part of TCR complex	+	+

CD, cluster of differentiation; ICAM, intercellular adhesion molecule; LFA, leukocyte function-associated antigen; TCR, T cell antigen receptor; VLA, very late activation antigen.

single-positive T cells as they emerge from the thymus, but its expression is upregulated on the first encounter with antigen stimulation in the periphery. Expression of the IL-7 receptor identifies a subset of effector T cells that are destined to become memory T cells. Several other markers have been shown to change on primary antigenic stimulation. Most notable for human T cells is CD45, in which an isoform known as CD45RA is expressed on naïve T cells, whereas CD45RO expression characterizes memory T cells (see Table 13-1). Using these markers it has been possible to identify a variety of differences between naïve and memory T cells. Activation of memory T cells appears to be more efficient than that of naïve T cells and not be absolutely dependent on co-stimulation. Memory T cells are also able to migrate to nonlymphoid tissues such as lung, skin, liver, and joints.⁹¹ Particularly interesting have been recent reports that the metabolic state of an effector T cell may profoundly affect which T cells survive to the memory state. Surprisingly, improved survival of memory T cells was conferred by agents such as rapamycin and metformin, which inhibit anabolic glycolytic metabolism and promote catabolic fatty acid metabolism.⁹²

T Helper Subsets

CD4 T cells can be further subdivided based on their cytokine profiles. This is a growing list that includes the classic Th1 and Th2 subsets, as well as Th17 cells, follicular helper T cells (T_{fh}), and regulatory T cells (T_{reg}) (Figure 13-6). Th1 cells participate in cell-mediated inflammatory reactions, activate macrophages, and produce IL-2, TNF, and IFN- γ . Th2 cells produce IL-4, IL-5, IL-6, IL-9, and IL-10. Further subsets of Th2 cells have been described that produce predominantly either IL-9 and IL-10 (Th9 cells, derived with TGF- β and IL-4) or IL-5 (Th5 cells, generated by antigen and IL-33) and are involved with allergic disorders. IL-4 and IL-5 are important B cell growth factors.⁹³ In addition, IL-4 promotes B cell secretion of IgG₁ and IgE, whereas IFN- γ drives IgG_{2a} production. Because Th1 and Th2 cells mediate different functions, the type of response generated can influence susceptibility to disease. A list of

cytokines and their properties is described in Chapter 26. These patterns have been best characterized during chronic infections. In general, a Th1 response helps eradicate intracellular microorganisms such as *Leishmania major* and *Bruceella abortus*,⁹⁴ whereas a Th2 cell response can better control extracellular pathogens such as the helminth *Nippostrongylus brasiliensis*.⁹⁵ The cytokine profiles of Th1 and Th2 cells are mutually inhibitory, such that the Th1 cytokine IFN- γ or IL-12 from APC suppresses Th2 responses and augments Th1 cytokine gene expression, whereas the Th2 cytokines IL-4, or IL-6 from APC, promote the opposite pattern. Polarization of the cytokine environment also occurs at the sites of inflammation in many autoimmune syndromes. Th2 skewing has been observed in models of systemic lupus erythematosus (SLE) in which increased levels of immunoglobulins and autoantibodies are typical, as well as in chronic allergic conditions such as asthma.⁹⁶ Frequently, however, the infiltrating lymphocytes exhibit a bias toward Th1 cytokines. This occurs with brain-infiltrating lymphocytes in multiple sclerosis and its animal model, experimental allergic encephalomyelitis (EAE),⁹⁷ β islet lymphocytes in diabetes,⁹⁸ and synovial lymphocytes in inflammatory arthritides.⁹⁹ Unlike the beneficial effects of Th1 responses during infections, these same cytokines can be quite deleterious in autoimmune disorders. Thus therapies based on inhibition of certain Th1 cytokines have been of considerable interest and often ameliorative such as anti-TNF treatment in rheumatoid arthritis.¹⁰⁰ Several cytokines can have pleiotropic effects, and predicting the effects of modulating their levels can be complex. For example, despite the tendency of IL-6 to promote a Th2 cytokine profile, blocking IL-6 is nonetheless beneficial in rheumatoid arthritis.¹⁰¹

A more recently described subset of IL-17-producing CD4⁺ T cells (Th17) has emerged as being critical for promoting a variety of autoimmune disorders. TGF- β , possibly originating from T_{reg}, accompanied by IL-6 (probably from dendritic cells), appears to be pivotal for the appearance of Th17 cells.⁶⁰ IL-23 may also be important for the survival, though perhaps not the appearance, of Th17 cells. Injections of IL-23 into skin produced increased IL-17 in the

epidermis and inflammatory lesions that resembled psoriasis.¹⁰² Th17 cells are increased in human psoriatic plaques,¹⁰² in rheumatoid arthritis synovial fluid, and in multiple sclerosis.¹⁰³ An additional CD4 T helper subset is found in B cell follicles of secondary lymphoid organs due to their expression of the B cell follicle homing receptor CXCR5.¹⁰⁴ These follicular helper T cells (Tfh) assist B cell activation and germinal center formation through expression of CD40L, IL-4, and IL-21. Dysregulation of Tfh function can result in autoantibody production and systemic autoimmunity.¹⁰⁵ Finally, CD4⁺FoxP3⁺ regulatory T cells (Treg) have been described earlier.

Molecular Mimicry

Perhaps the oldest concept in autoimmune mechanisms is that of molecular mimicry, the notion that the response of the immune system to a foreign substance may provoke cross-reactivity to a self-protein. This is best established in rheumatic heart disease, where a B cell antibody response to a group A streptococcal cell wall component can precipitate a cross-reactivity to cardiac myosin. Similarly for T cells, investigators used the peptide sequence of myelin basic protein (MBP) recognized by specific T cell clones from patients with multiple sclerosis to search a database of infectious agents. Some of the candidate sequences obtained were able to stimulate the MBP-reactive T cell clones.¹⁰⁶ This suggested for the first time that T cells responding to an infectious agent might manifest cross-reactivity to self-peptides. Another example is one of the outer surface proteins of *B. burgdorferi* known as OspA, which may trigger a cross-reactive T cell response.¹⁰⁷ A T cell immunodominant peptide of OspA was identified in a subset of HLA-DR4 patients who are more resistant to antibiotic treatment and manifest an antibody, as well as a T cell response, to OspA.¹⁰⁸ Using a sequence algorithm to identify homologous peptides that bind the DR4 pocket, a sequence in LFA-1 that bound DR4 and stimulated a T cell response from these OspA-reactive patients was identified.¹⁰⁷ The technology of peptide/MHC tetramers discussed earlier will enable investigators to determine whether a given subpopulation of T cells within an inflammatory synovium might manifest dual specificity for both a foreign pathogen and a cross-reacting self-protein.

Death of T Cells

The rapid removal of the effector T cells following clearance of the infection is as important as the initial clonal expansion of responding T cells for the health of the organism. Failure to clear activated lymphocytes increases the risk of cross-reactivity with self-antigens and a sustained autoimmune reaction. To ensure that resolution of an immune response occurs rapidly, a number of processes promote active cell death of clonally expanded T cells. One means to control T cell proliferation is through limited availability of growth factors. On activation, T cells express receptors for various growth cytokines for approximately 7 to 10 days but only produce cytokines for a more limited period. This results in an unstable situation where T cells tend to outgrow the availability of cytokines. T cells expressing IL-2R, for example, in the absence of IL-2 will rapidly undergo

programmed cell death. Another method is restimulation of TCR on actively dividing T cells, which triggers a death cascade known as *activation-induced cell death* (AICD).

The discovery of a family of death receptors expressed by T cells elucidated an additional regulatory process. These molecules are described more extensively in Chapter 27 on cell survival and are only discussed here as they relate to T cell function. The best described of these is Fas (CD95). Both Fas-deficient mice and humans bearing Fas mutations (Canele-Smith syndrome)¹⁰⁹ manifest a profound lymphadenopathy accompanied by an autoimmune diathesis. This underscores the importance of efficiently removing T cells after their activation. Nearly all cells have some level of surface Fas, whereas expression of its ligand (FasL) is restricted primarily to activated T cells and B cells. Consequently, regulation of Fas-mediated apoptosis is to a large extent under the governance of the immune system. FasL expression has also been reported for certain components of the eye, the Sertoli cells of the testis, and perhaps some tumors.¹¹⁰ Expression of FasL by these nonlymphoid cells is thought to prevent immune responses at sites where such inflammation might cause tissue damage. For years immunologists have been aware of these so-called “immune privileged” sites within which immune responses are difficult to initiate.

During T cell activation, expression of FasL is rapidly induced and the ability to kill Fas-sensitive target cells is easily demonstrated. Yet expression of surface FasL protein has been difficult to demonstrate. This may be due to a sensitivity of surface FasL to certain proteinases, which results in its rapid cleavage and release from the cell, in a manner similar to the release of another member of the Fas family, TNF. Resting T cells are not sensitive to Fas-induced death but must first enter the cell cycle for approximately 3 days. During this period, the cellular level of an endogenous inhibitor of Fas known as *c-FLIP* is downregulated and this presumably allows Fas signaling to progress.¹¹¹ Thus *c-FLIP* may function to protect resting T cells from unnecessary death and restrict apoptosis to activated T cells in order to limit their expansion.

The sequence of T cell activation followed by cell death is graphically displayed following the administration to mice of bacterially or virally derived compounds called *superantigens*. Superantigens activate T cells by directly crosslinking MHC class II molecules with particular β -chain V families of the TCR (see Figure 13-3A). The superantigen staphylococcal enterotoxin B (SEB) strongly activates V β 8⁺ T cells.¹¹² This initiates a rapid expansion of V β 8⁺ T cells over 2 to 3 days followed by an equally rapid loss of these cells, such that by day 7 few V β 8⁺ T cells remain. A similar process of T cell activation occurs in the human disease toxic shock syndrome in which a related staphylococcal toxin, TSST, stimulates the expansion of V β 2⁺ T cells.¹¹³ The devastating illness that results from this profound activation of a large proportion of T cells underscores the need to rapidly eliminate activated T cells. At least some of the damage in toxic shock syndrome likely results from the extensive T cell expression of FasL and TNF, particularly in certain tissues such as the liver. Hepatocytes are exquisitely sensitive to damage by these ligands. Activation of T lymphocytes leads to homing to the liver, and administration of antigen to TCR transgenic mice can yield a syndrome

resembling autoimmune hepatitis.¹¹⁴ Thus certain autoimmune disorders may result from the death or damage of “innocent bystander” cells as a consequence of the migration of activated T cells to an organ and nonspecific damage due to the expression of FasL family members.

Although it was initially assumed that Fas would largely regulate this process, Fas-deficient mice eliminate T cells activated by either traditional antigens or superantigens nearly as efficiently as wild-type mice. Rather, proapoptotic members of the Bcl-2 family, Bim, Bad, and Bax, appear to regulate death in vivo from cytokine withdrawal or following acute foreign antigen stimulation as with certain infections.¹¹⁵ These molecules are related to the cell survival molecule, Bcl-2, but are more truncated, containing only the BH3 domain of Bcl-2, and hence their designation as the “BH3-only” family. They function as sentinels within the cell in that they are attached to various cytoskeletal proteins and organelles and sense cellular damage. If damage occurs, they are released from these sequestered areas and migrate to the mitochondria to inhibit the survival function of Bcl-2.¹¹⁵ By contrast, Fas serves to eliminate T cells following chronic TCR stimulation as occurs in homeostatic proliferation or chronic infections.^{116,117}

T Cells at Sites of Inflammation

The observation that T cells infiltrate target organs in autoimmune diseases such as rheumatoid arthritis, type 1 diabetes mellitus, and multiple sclerosis quickly led to an analysis of T cell subsets and, more recently, to a more detailed study of the T cell repertoire based on TCR expression. In many of these disorders, the known HLA class II association is paralleled by a predominant, though by no means exclusive, infiltration of CD4⁺ T cells bearing a broad TCR repertoire.¹¹⁸ Many of these CD4⁺ T cells also manifest a Th1-like cytokine profile as discussed earlier.⁹⁷⁻⁹⁹ Evidence for the importance of these CD4⁺ cells derives from numerous studies showing the efficacy of CD4 depletion in animal models of these disorders.¹¹⁹ A parallel situation has often occurred in humans with these autoimmune diseases who concurrently become infected with HIV. The CD4 depletion occurring during AIDS can actually ameliorate rheumatoid arthritis.¹²⁰ However, the resulting CD8 predominance during HIV infection has also frequently resulted in exacerbation of psoriatic arthritis and Sjögren's syndrome, suggesting the CD8⁺ subset of T cells may be important in these disorders.¹²⁰ Given the previously mentioned effect of the metabolic state of T cells on their survival, it will be highly informative in future studies to examine the metabolic state of T cells at sites of autoimmune tissue inflammation versus that observed in secondary lymphoid tissues during infections. Conceivably the cytokine environment of inflamed tissues may confer a metabolic state that favors T cell survival compared with states of infection.

KEY POINTS

Immunoglobulins (Igs) are key to B cell function by serving as both an antigen receptor and a major secreted product. The variable region binds antigen and is generated by random rearrangement of gene segments to give rise to numerous specificities. The constant region defines the isotype and mediates effector functions.

Surface Ig is the major component of the B cell receptor, which regulates B cell selection, survival, and activation. Secreted immunoglobulin mediates antigen neutralization and opsonization with uptake by phagocytic cells, complement activation, and cellular activation or inhibition through engagement of receptors for the Fc region of Ig.

B cells are generated from hematopoietic precursors in the bone marrow and undergo several stages of maturation and selection before becoming immunocompetent, naive B cells that reside in peripheral lymphoid organs. After antigen activation, B cells differentiate to memory cells and Ig-secreting plasma cells.

Follicular B cells respond to protein antigens in a T cell-dependent fashion and are the major source of B cell memory. B1 and marginal zone B cells are less dependent on T cell help, respond primarily to polysaccharide antigens, and display limited heterogeneity of the B cell receptor.

Autoreactive B cells are generated in all individuals. Multiple checkpoints extinguish autoreactive B cells during early and later stages of B cell development. One or more of these checkpoints is breached in autoimmune-prone individuals, leading to the maturation and activation of autoreactive B cells.

OVERVIEW: B CELLS AND HUMORAL IMMUNITY

Numerous cells comprise the immune system and are required to generate innate and adaptive immune responses. Adaptive responses are characterized by immunologic memory generated during first exposure to antigen, thereby permitting a rapid response to antigen following subsequent exposure.

B cells (Figure 14-1) are lymphocytes that recognize antigens through a molecule called the B cell receptor. The B cell receptor is composed of a surface immunoglobulin molecule, which recognizes the antigen, and two associated proteins, which transduce the signal. On encounter with its antigen, a B cell begins a process of activation leading to antibody secretion and memory formation regulated by interplay with antigen-activated T cells, dendritic cells,

B Cells

soluble factors, and in some cases follicular dendritic cells. Both T and B lymphocytes can differentiate from naïve to memory cells, but only B cells have the capacity to fine tune their antigen receptor structure to increase its specificity and affinity, giving rise to more effective antibodies. Beyond immunoglobulin secretion, B cells regulate the immune response by cytokine secretion and antigen presentation to T cells in the context of class II molecules.

Importantly, much of the knowledge of B cell biology has been generated in mouse models. However, in this chapter, human B cell biology is described whenever possible.

IMMUNOGLOBULINS: STRUCTURE AND FUNCTION

The Ig molecule is critical to all aspects of B cell biology when anchored to the B cell membrane. Termed *B cell receptor* (BCR), it contributes to B cell maturation and survival and initiates an activation cascade following contact with antigen. At the end of the activation process, B cells can acquire the ability to secrete large amounts of Ig, intended to neutralize the antigen that elicited the response.

Structurally, Igs, also referred to as *antibodies*, are composed of four polypeptide chains: two identical light (L)-chains with a molecular weight of approximately 25 kDa and two identical heavy (H)-chains of 50 to 65 kDa. Each of the chains contains a folding motif that is highly conserved among proteins of the immune system, the “Ig domain.” These domains constitute the backbone of the Ig molecule and make for the interface along which the polypeptide chains pair (Figure 14-2). The quaternary structure of an immunoglobulin molecule assumes a Y-shaped conformation, which contains two functional moieties: two identical antigen-binding regions or variable regions, which are the arms of the “Y,” and a constant region, which is the base of the “Y.”¹

This definition of functional moieties derives from early studies analyzing proteolytic fragments of Ig molecules. Cleavage with papain generates two identical fragments that retain antigen-binding capacity and hence are named Fab, as well as a distinct crystallizable fragment Fc that mediates immune effector functions but is unable to interact with antigen.²

The antigen-binding regions are formed by pairing of the variable domain of the L-chain (V_L) to the variable domain of the H-chain (V_H). In contrast to the rest of the molecule, there is a great diversity in the amino acid sequence of the variable domains, which allows for a broad repertoire of antibody molecules that can recognize a wide array of antigens. Within the variable region of the Ig molecule are discrete regions, known as *complementary determining regions*

Figure 14-1 Micrograph of a B cell. (Courtesy of Professor Peter Groscurth, University of Zurich.)

(CDRs) that make direct contact with antigen. The amino acid sequences of the CDR are highly variable and are flanked by more conserved amino acid sequences called *framework regions*. The H- and L-chain molecules each contain three CDRs and four framework regions (see Figure 14-2). The minimal antigenic determinant recognized by

Figure 14-2 Schematic of the antibody molecule. An antibody monomer consists of two heavy (H)-chain molecules covalently linked to two light (L)-chain molecules. The variable region is composed of the V_H and V_L domains of the H and L chains, respectively. Within the V_H and V_L domains are four framework regions (FWRs) and three complementarity-determining regions (CDRs), which together make up the antigen-binding pocket. Papain digestion generates the Fab portion, which consists of V_H , C_{H1} , V_L , and C_L domains, and pepsin digestion generates two covalently linked Fabs, known as the $F(ab')_2$. The Fc region of the H-chain constant region, which mediates immune effector functions, consists of the hinge domain (only in IgG, IgA, and IgD), which increases flexibility and C_{H2} and C_{H3} domains.

the H and L CDR is known as an epitope, which may be a continuous or discontinuous region on a protein, carbohydrate, lipid, or nucleic acid. The presence of two identical variable regions in a single Ig molecule confers the capacity to interact with repetitive antigenic determinants present in multivalent antigens (i.e., polysaccharides) or two separate antigen molecules containing the same antigenic determinant.¹

The constant region directs the Ig effector functions that mediate the killing and removal of invading organisms and both the activation and homeostasis of the immune system. Strictly speaking, the constant region is formed by the constant domain of the L-chain (C_L), which is paired to the first constant domain of the heavy chain (C_{H1}), and the remaining constant domains of the two heavy chains (C_{H2} and C_{H3} and C_{H4} in IgM), paired to each other. However, most of the functions associated with the constant region are mediated by the constant domains of the H-chain.

Immunoglobulin Constant Region

The specific binding interactions that occur between the Ig variable region and antigen may be sufficient to block microbial infectivity or neutralize toxins. However, the ability to eliminate pathogens is mediated by the Fc portion of the molecule. The Fc regions of antigen-antibody complexes are made accessible to serum factors that comprise the complement cascade or to cytotoxic and phagocytic cells that mediate the destruction and removal of pathogens. In mice and humans, there are five different types of H-chain constant regions, or isotypes, designated IgM (μ), IgD (δ), IgG (γ), IgA (α), and IgE (ϵ)³; each is encoded by a distinct constant region gene segment present in the H-chain locus of chromosome 4 in humans or 12 in mice. Each isotype is capable of specific effector functions, and each cellular receptor for Ig initiates a distinct intracellular signaling cascade. The number of C_H domains, presence of a hinge region to increase flexibility between Fab regions, serum half-life, ability to form polymers, complement activation, and Fc receptor binding vary among isotypes. Characteristics of the different Ig H-chain isotypes are presented in Table 14-1.^{1,3,4} These isotypes may also differ in the intracellular signaling they initiate when bound by antigen in their membrane-associated form on the B cell. It should be noted that the interplay between antibodies and the cells that bear the Fc receptors extends beyond pathogen clearance and shapes the immune response by mediating activation or inhibition of specific cell types⁵ and by mediating cell death.⁶

Immunoglobulin M

IgM is the first isotype expressed in developing B cells and the first antibody secreted during a primary immune response. It is found predominantly in serum but is also present in mucosal secretions and breast milk. Because the process that increases antibody affinity for a particular antigen (affinity maturation) has not yet been initiated during the early stages of a primary immune response, IgM antibodies usually exhibit low affinity. Their low affinity is balanced by the fact that most of the secreted IgM exists in pentameric form, generating multiple binding sites,

Table 14-1 Properties of Human Immunoglobulin (Ig) Isotypes

Characteristic	IgM	IgG	IgA	IgE	IgD
Structure	Pentamer, hexamer	Monomer	Dimer (IgA ₂), monomer (IgA ₁)	Monomer	Monomer
C _H domains	4	3	3	4	3
Serum values (mg/mL)	0.7-1.7	9.5-12.5	1.5-2.6	.0003	.04
Serum half-life (days)	5-10	7-24	11-14	1-5	2-8
Complement activation (classic)	Yes	Yes	No	No	No
FcR-mediated phagocytosis	No	Yes	Yes	No	No
Antibody-dependent cell mediated cytotoxicity	No	Yes	No	No	No
Placental transfer	No	Yes	No	No	No
Presence in mucosal secretions	Yes	No	Yes	No	No
Main biologic characteristic	Primary antibody response	Secondary antibody responses	Secreted immunoglobulin	Allergy and parasite reactivity	Marker for naïve B cells

providing high avidity for antigen and assisting the binding of large, multimeric antigens. IgM also exists as a monomer and a hexamer, but only the pentameric form is linked by the polypeptide called joining (J)-chain. The J-chain allows the active transport of IgM to mucosal secretions.⁷

Many of the biologic functions of IgM are mediated by its ability to activate the classic complement pathway.¹ The complement cascade is composed of a series of enzymes that, on activation, mediate the removal and lysis of invading organisms. Deposition of antibody molecules or complement components on the surface of the antigen assists phagocytosis. Proteins such as antibody and complement that enhance phagocytosis are called *opsonins*. Once the complement cascade has been activated, monocytes, macrophages, or neutrophils engulf opsonized particles through specific receptors present on phagocytic cells such as CD21, which recognizes fragments of the C3 complement component. Activation of the complement pathway also results in the generation of the membrane attack complex, which is composed of late complement components and directly lyses C3-opsonized pathogens. Because activation of the classic complement pathway requires Fc regions to be spatially close, but also exposed, multimeric IgM is a potent activator of the classic complement pathway once it has bound its antigen. For example, hexameric IgM is between 20 and 100 times more potent as an inducer of complement activation than monomeric IgM.⁸

Immunoglobulin G

IgG is the most common isotype found in serum, comprising about 70% of the circulating antibody. IgG antibodies are usually of higher affinity than IgM antibodies and predominate in a secondary or memory immune response.

In humans there are four subclasses of IgG: IgG1, IgG2, IgG3, and IgG4. IgG1 and IgG3 arise in response to viral and protein antigens. IgG2 is the main antibody present in response to polysaccharide antigens, and IgG4 participates in responses to nematodes and is observed in chronic antigenic stimulation.⁹

All IgG subclasses exist as monomers and have a high structural similarity; however, minor differences make for distinct biologic effects. IgG3 and IgG1 are potent

activators of the classic complement pathway, and IgG2 can initiate the alternative complement pathway (see Chapter 23).

All IgG subclasses engage specific Fc gamma receptors (FcγRs) present on dendritic cells, macrophages, neutrophils, and NK cells. The FcγRs on phagocytic cells, when cross-linked, mediate the removal of immune complexes from circulation and initiate antibody-dependent, cell-mediated cytotoxicity resulting in the release of granules that contain perforin, a pore-forming protein, and enzymes known as *granzymes* that induce programmed cell death (apoptosis) of target cells.^{10,11} FcγR engagement also allows the internalization and subsequent presentation of antigens in the context of MHC class II molecules.

Because IgG antibodies are the only ones that cross the placental barrier, they are critical for the survival of newborns. The transport of IgG from the maternal circulation into the fetal blood supply is mediated by the FcRn receptor.¹² FcRn is also responsible for the long half-life of IgG in serum by blocking IgG catabolism.¹³

Immunoglobulin A

Despite its relative low concentration in serum, more IgA is produced than all other isotypes combined. Most IgA exists as secretory IgA (SIgA) in mucosal cavities and in milk and colostrum, and only a small fraction is present in serum. Two subclasses of IgA exist in humans: IgA1 and IgA2. IgA1 is mainly produced as a monomer. In contrast, polymeric IgA2 is produced along mucosal surfaces.¹⁴

Polymeric IgA exists mainly as a dimer and includes a J-chain (the same chain that links pentameric IgM). It is captured by the polymeric immunoglobulin receptor (pIgR) that is expressed on the basolateral surface of the epithelial cells and then transcytosed to the apical side. Release of IgA into mucosal secretions requires cleavage of the pIgR; a fragment known as the secretory component (SC) remains associated with secreted IgA and protects it from the action of proteases and increases its solubility in mucus, where it neutralizes toxins and inhibits the adherence of secreted IgA-coated microorganisms to the mucosal surface.¹⁵

People with IgA deficiency have reduced levels of both serum and secreted IgA and are prone to respiratory tract

and diarrheal infections, as well as an increased incidence of autoimmune disorders.¹⁶ Fc α R, present in the surface of neutrophils and macrophages, has been suggested to play a regulatory role in the immune system; it is not clear if the autoimmune manifestations in IgA-deficient patients are a consequence of the absence of the regulatory loop played by engagement of Fc α R.¹⁷

Immunoglobulin E

IgE is involved in protection against parasitic infections but also triggers immune responses associated with allergic reactions. Only a small amount of IgE is detectable in serum, where it exists as a monomer.¹⁸ Mast cells and basophils express a high-affinity IgE Fc receptor (Fc ϵ RI) that binds free IgE. Cross-linking of the Fc ϵ R by antigen binding to the IgE induces degranulation and release of histamine, proteases, lipid mediators such as prostaglandin D₂ and leukotrienes, many of which are associated with anaphylaxis.

Immunoglobulin D

The role of IgD in the humoral response has been the subject of multiple speculations. IgD is found predominantly as a membrane immunoglobulin on the surface of mature naïve B cells. Soluble IgD is scarce in serum; however, IgD-producing plasma cells are found in tonsils and tissue associated with the respiratory tract. High levels of secreted IgD can be found in individuals with immunodeficiencies.¹⁹

Light Chains

There are two distinct L-chain polypeptides, designated kappa (κ) and lambda (λ). L-chains contain a variable and a single constant domain. Even though there are two L-chain isotypes, there is no known function associated with the L-chain constant region. The κ chain is used more often than the λ chain in human (65%) and mouse (95%) Ig molecules.²⁰

Immunoglobulin Variable Region

The recognition of a virtually unlimited number of antigens requires a mechanism to generate Ig molecules with similarly broad specificities. The molecular basis of this process has been known for several years.²¹ First, the Ig molecule is composed of both heavy and light chains. These chains are encoded within distinct genetic loci residing on separate chromosomes; the H-chain locus is on human chromosome 14,²² the κ -chain locus is on chromosome 2, and the λ -chain locus is on chromosome 22.²³

Within each locus, gene segments encode both the variable and constant regions of the Ig molecule. The H-chain variable region is encoded by a variable (V_H), diversity (D_H), and a joining (J_H) segment. The L-chain is encoded by either V_κ and J_κ or V_λ and J_λ segments; it does not contain D segments. The human H-chain locus contains from 38 to 46 V_H , 23 D_H , and 9 J_H functional genes (these numbers represent a typical haplotype, but vary among individuals). The κ -chain locus contains approximately 31 to 35 V_κ genes and 5 J_κ functional genes; the λ -chain locus contains 29 to 32 V_λ genes and 4 or 5 J_λ functional genes.²⁴

Generation of Immunoglobulin Diversity

In a developing B cell, different V_H , D_H , and J_H or V_L and J_L gene segments are randomly combined to generate a large number of different Ig molecules (Figure 14-3). This process, known as V(D)J recombination, occurs in the primary lymphoid tissue, in the absence of antigen stimulation and must be successful to continue with B cell maturation. Here, we present the molecular process, and later the functional and developmental consequences are discussed (see B Cell Development).

V(D)J recombination happens sequentially, beginning with the joining of one D_H segment to one J_H . Following this, a V_H segment will be targeted to the rearranged D_HJ_H fragment. The absence of an in-frame recombination leads to recombination of the second allele. Light chain recombination also occurs stepwise. First, the kappa locus is rearranged; in absence of a productive κ -chain rearrangement, the lambda locus undergoes recombination.²⁵

The recombination machinery is composed of specific enzymes including Recombination-Activating Gene 1 (RAG-1) and the Recombination-Activating Gene 2 (RAG-2). The complex recognizes recombination signal sequences (RSS) that flank the V, D, and J gene segments. These highly conserved sequences are composed of a palindromic heptamer (7 base pairs) followed by deoxyribonucleic acid (DNA) spacers that are 12 or 23 base pairs in length and an AT-rich nonamer.²⁶ Once the complex recognizes its target, it generates double-stranded DNA (dsDNA) breaks at the RSS sites. Next, the cellular DNA repair complex recognizes and joins the cleaved segments.

The random recombination that occurs among V, D, and J gene segments can generate a diverse Ig repertoire without the need for a large number of germline H- and L-chain genes. During H-chain recombination, nucleotides may be added at V_HD_H and D_HJ_H junctions by the enzyme terminal deoxynucleotidyl transferase (TdT). These non-germline-encoded sequences are known as *N additions*. As long as these nucleotide changes do not disrupt the reading frame or lead to the incorporation of premature stop codons, the random addition of N sequences increases the diversity of the amino acid sequence. Further, imprecise ligation at the coding junctions may result in the loss of nucleotides, thereby also enhancing diversity.

B CELL DEVELOPMENT

The aim of the maturation process is to generate a pool of mature B cells with a diverse repertoire of Ig specificities that can recognize foreign and pathogenic antigens without compromising the integrity of the self. Therefore the process of generation of Ig diversity is coupled with the censoring of autospecificities.

B cells, as all cells in the hemopoietic lineage, begin with the differentiation of noncommitted, undifferentiated CD34⁺ hematopoietic stem cells to lymphopoietic precursors with restricted lineage potential. These cells, known as *common lymphoid progenitors* (CLP), have the potential to give rise to NK, T, and B cells. Early B cell progenitors begin to express genes for DNA rearrangement, as well as B cell program transcription factors. Multiple transcription factors act in concert, but Ikaros, E2A, EBF, and Pax5 appear to be

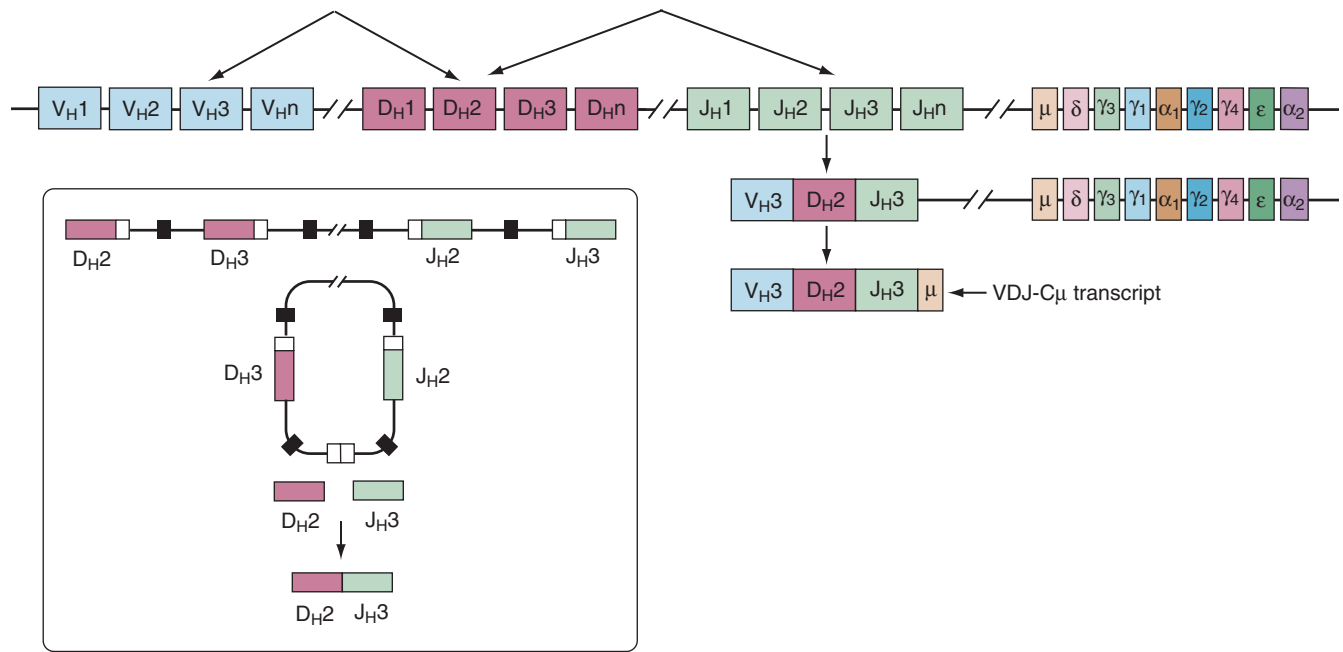

Figure 14-3 V(D)J recombination at the immunoglobulin gene locus. V(D)J recombination at the heavy (H)-chain locus is depicted at the top. A single V_H gene segment randomly recombines with a D_H and J_H gene segment residing on the same chromosome. Following V_HD_HJ_H recombination, a transcript containing the IgM H-chain constant region gene (C_μ) is generated. The *inset* represents an example of VDJ recombination occurring between a single D_H and J_H gene segment. The *white squares* represent the heptamer, and the *black squares* represent the nonamer recombination recognition sequences. Following recognition and cleavage of these sequences, the coding junctions of the rearranged D_H and J_H gene segments are ligated. A V_H gene segment then recombines with the rearranged D_HJ_H segment. Light (L)-chain rearrangement is mediated by the same mechanism.

the most important in B cell development.²⁷ Pax5 is considered the master transcriptional control for B cells because it is induced in early stages of B cell commitment and plays a dual role by repressing genes required for differentiation to the myelomonocytic lineage and activating B cell-specific genes such as Ig genes, CD19, and signaling molecules.²⁸

Niches of Human B Cell Lymphopoiesis

The development of undifferentiated hematopoietic stem cells (CD34+) into mature B cells begins in the first weeks of uterine life. By the eighth gestational week, early B cell precursors can be identified in the fetal liver and omentum. From gestational week 34 and through adulthood, the bone marrow is the primary site of lymphopoiesis.²⁹

It has been unequivocally established that there are differences between the B cells that originate during fetal and adult lymphopoiesis in mice, and it is becoming clear that these differences extrapolate to human lymphopoiesis as well. B cell precursors are susceptible to estrogen, and the maturation of maternal B cells is arrested in the pro-B cell stage during pregnancy; in contrast, fetal B cell precursors lack estrogen receptors and consequently are unaffected by exposure to hormones.³⁰ B cells originating during prenatal life have a bias in the usage of D_H and J_H gene segments, and this, along with reduced expression of the enzyme TdT, leads to a more restricted repertoire with shorter CDR3s.³¹

Whether during fetal or adult lymphopoiesis, the maturation of B cells from pluripotential progenitors is contingent on the presence of stromal cells that provide both contact-dependent and soluble signals. Although the nature

of the interactions provided by the stromal cells to create a lymphopoiesis-permissive environment is still largely unknown, they include both survival and proliferative signals. The stromal-derived factor-1 (SDF-1) is required for the homing of the early B cell precursors to sites of lymphopoiesis but also promotes differentiation.³² Interactions between VCAM-1 on the membrane of the stromal cells and its counterpart, VCAM-4, on early B cell progenitors are required for B cell differentiation. The molecules IL-7, IL-3, and the Flt3 ligand promote B cell lymphopoiesis, although IL-7 appears to be dispensable for human B cell development. Matrix molecules in the microenvironment such as heparan sulfate proteoglycan are assumed to “trap” critical soluble factors.³³

B Cell Ontogeny

The stages of B cell development are defined by the state of Ig gene rearrangement and the expression of intracellular and surface proteins. The nomenclature and classification of particular stages vary slightly among different laboratories working in this field. For simplicity, we have divided the stages of B cell lymphopoiesis into early B cell progenitors, pro-B, pre-B, immature, transitional, and mature naïve cell (Table 14-2).

When a CLP begins to transcribe RNA coding for proteins required for B cell maturation, E2A and EBF, the cell becomes an early B cell progenitor. Once these two transcription factors are expressed, they enable transcription of the proteins involved in the recombination machinery (RAG1/2). The beginning of D to J recombination marks the progress to a pro-B stage.

Table 14-2 Human B Cell Maturation Markers during B Cell Development

Marker	HSC	Pro-B	Pre-B	Immature	Transitional 1	Transitional 2	Plasma

Pro-B Cells

This stage is defined by the rearrangement of the heavy chain gene segments and synthesis of a μ -polypeptide. Pro-B cells are dependent on interactions with endothelial cells present in the stroma. The VLA-4 integrin receptor and CD44, which both mediate adhesion to stromal cells, are highly expressed at this stage and are believed to be important for continued development.³⁴ Pro-B cells also express high levels of Bcl-2, a molecule that protects cells from apoptosis. At the onset of the pro-B cell stage, the variable gene segments of both H- and L-chain loci are in the *unrearranged germline configuration* but accessible to the recombination machinery. A D_H gene segment on one H-chain chromosome rearranges with a J_H gene segment residing on the same chromosome, often with the inclusion of nontemplate nucleotides at the junction of these two segments. Next, a V_H gene rearranges to the D_HJ_H gene fragment. Completion of V_HD_HJ_H gene rearrangement leads to the generation of an H-chain transcript that also contains the IgM constant region (C _{μ}), which is the constant region gene most proximal to the variable region genes on the chromosome (see Figure 14-3).

The generation of a μ -polypeptide and its subsequent expression on the surface of the cell, together with a surrogate light chain formed by the $\lambda 5$ and Vpre-B polypeptides as well as the Ig α /Ig β dimer, a complex known as the pre-B cell receptor (pre-BCR), marks the end of this phase of gene recombination. This constitutes a critical developmental checkpoint and the entrance to the next developmental stage known as the *pre-B cell*.³⁵ The requirement for a pre-BCR complex ensures that B cells without a productive H-chain will not undergo further differentiation.

The pre-BCR transduces a signal that the VDJ rearrangement was successful and halts recombination of the second H-chain allele. This process, known as *allelic exclusion*, ensures that all Ig molecules generated within a single B cell are identical and have the same antigenic specificity. If no

μ -chain is generated, rearrangement is initiated on the other chromosome. If the second rearrangement also results in a nonproductive H-chain molecule, the absence of pre-BCR-mediated signal induces apoptosis. The odds of generating a productive rearrangement are one in three, and consequently, approximately 50% of the cells that begin recombination will be unable to proceed along a developmental pathway.

Pre-B Cells

The pre-B cell stage is characterized by light chain recombination. Initiation of this stage requires the presence of the pre-BCR and functional signal transduction machinery.

At the onset of the pre-B cell stage, the expression of the pre-BCR induces a proliferative burst that generates daughter cells with the same heavy chain and potential for multiple specificities within daughter cells, each of which may produce a different light chain. It is unknown if expression of the pre-BCR and tonic signaling is enough to trigger these events³⁶ or if a ligand must engage the pre-BCR.^{37,38} Either way, targeted disruption of genes encoding the pre-BCR complex such as the IgM transmembrane constant region domain, $\lambda 5$, or the Ig α and Ig β accessory molecules results in a profound decrease in developing B cells. Also, defects in the adapter molecule BLNK, $\lambda 5$, or the tyrosine kinase Btk lead to a serious impairment in pre-B cell maturation.

The expression of the pre-BCR is transient. After the proliferative burst, the μ -heavy chain is present only in the cytoplasm as the pre-B cell rearranges an L-chain. The general rearrangement process is similar to V(D)J rearrangement and is dependent on Rag1/2 expression. Because TdT is not expressed in this stage, L-chains do not usually contain N sequences at the V_LJ_L junction. At the end of this process, pairing of the newly minted light chain with the μ -heavy chain leads to the surface expression of an IgM molecule, complexed with Ig α and Ig β , to form the B cell

receptor (BCR). It is believed that surface expression of the BCR on immature B cells transduces signals that enforce allelic exclusion at the L-chain locus and downregulate expression of the RAG genes. This immature B cell has completed the gene rearrangement process and is now subject to repertoire selection.³⁹

Immature B Cells

Once B cells express surface IgM in the bone marrow, they are subject to *repertoire censoring*. During this stage, cross-linking of the BCR by antigen leads to the activation of one of several tolerance mechanisms. These mechanisms include deletion, receptor editing, and anergy and diminish the fraction of autoreactive cells present in the mature repertoire (see later discussion on negative selection).

During the maturation process in the bone marrow, the cells become less dependent on interactions with the stroma and move toward the bone cavity. Once they express IgM, they begin to move into blood, where they are called *transitional cells*.

Peripheral B Cell Subsets

As B cells mature and their dependence on stromal cells decreases, they leave the bone marrow and finish their maturation in the spleen before homing to other lymphoid tissue such as the lymph nodes, tonsils, and Peyer's patches of the intestine. It is in these secondary lymphoid organs where mature B cells interact with foreign antigen and specific humoral immune responses are activated.

Transitional B Cells

Once immature B cells egress from the bone marrow, they are called *transitional cells*. These cells are the earliest B cells found in the periphery in healthy subjects and move to the spleen to finish their maturation.

Transitional cells are the last B cell subpopulation that expresses the developmental marker CD24. At this stage B cells begin to express surface IgD, which harbors the same specificity as the IgM because the IgD heavy chain is encoded by the same VDJ fragments as IgM but expresses the C δ instead of the C μ domain. It is the expression of IgD that separates transitional cells into two different maturation stages. Transitional 1 (T1) B cells that do not express IgD are the recent bone marrow emigrants, and transitional 2 (T2) B cells that begin to express IgD represent the subsequent maturational stage.⁴⁰ The existence and functional characteristics of a third transitional stage (T3) are still debated.

Transitional cells constitute a stage subject to multiple regulatory processes. First, transitional cells must compete with naïve B cells already present in the periphery for a developmental niche. Transitional B cells are extremely dependent on a B cell survival factor known as *B cell-activating factor of the tumor necrosis factor family* (BAFF or BLyS). In its absence, B cell development does not progress beyond the T1 stage.⁴¹ Second, T1 transitional cells are still highly susceptible to tolerance induction following BCR cross-linking. In T1 cells cross-linking of the BCR *ex vivo*

has been shown to lead to cell death, whereas T2 cells respond to BCR cross-linking by proliferation and differentiation to the mature naïve B cell stage.

BAFF Family of Cytokines

The cytokine milieu surrounding the B cell is diverse and spatially and temporarily regulated. Although B cells are modulated by multiple cytokines, in recent years two members of the TNF family, BAFF and APRIL, have emerged as key survival factors, particularly at two regulatory points in development and differentiation: the transition from an immature to a naïve B cell in the periphery and the survival of the newly produced plasma cells. BAFF (B cell-activating factor, BLyS) and APRIL (A proliferation-inducing ligand) are proteins produced by cells that take part in the innate response such as macrophages and dendritic cells, as well as stromal cells, and are present as membrane-bound proteins or soluble trimers. They have three known receptors (BAFF-R, TACI, and BCMA) that are present on the membrane of B cells from the T2 stage to their final differentiation to plasma cells. BAFF binds the three receptors, whereas APRIL binds only TACI and BCMA. BAFF induces survival and activation of B cells when bound to BAFF-R, whereas BAFF signaling through TACI decreases the size of the B cell pool. APRIL does not participate in B cell homeostasis but seems critical to the survival of plasmablasts in the bone marrow.⁴²

Enhanced survival and activation of autoreactive B cells have been demonstrated in mice that overexpress BAFF.⁴³ An increase in serum levels of BAFF has been observed in some patients with lupus, rheumatoid arthritis, and Sjögren's syndrome and is thought to contribute to pathogenesis because autoreactive B cells have a survival advantage in the presence of excess BAFF⁴⁴ (Figure 14-4).

Naïve B Cells

The final stages of maturation that occur in the spleen and give rise to the naïve B cell subset have not been fully elucidated, but the prevailing theory is that T2 B cells give rise to the circulating mature naïve cell population. In the mouse, two populations of phenotypically and functionally different naïve B cells are recognized: follicular and marginal zone B cells. Human naïve B cells comprise 60% to 70% of the circulating B cell repertoire and populate the spleen and lymph nodes. They include the equivalent of mouse follicular B cells and represent the circulating, non-antigen exposed B cell subpopulation characterized by surface IgM and IgD expression, lack of CD27, and the presence of the membrane transporter ABC.⁴⁵ There is also a population in blood of IgM+, CD27+ B cells that have been likened to marginal zone B cells, which do not recirculate in the mouse.⁴⁶

Marginal Zone B Cells

Marginal zone (MZ) B cells are a population of noncirculating mature B cells located in the marginal zone of the rodent spleen. In rodents, MZ B cells present clear phenotypic and functional differences to the cells present in the follicles, responding to blood-borne pathogens and to repetitive

Figure 14-4 The BAFF family of cytokines and their receptors. BAFF and APRIL are expressed as membrane-bound proteins that can be cleaved by proteases to produce the soluble proteins. BAFF might bind the three known receptors: BAFF-R, TACI, and BCMA. APRIL only binds to BCMA and TACI.

antigenic structures such as the ones present on polysaccharide antigens.

In the human spleen, the structural definition of the marginal zone does not correspond exactly to the area surrounding B cell follicles. However, there is a population with the functional characteristics of mouse MZ B cells: low activation thresholds, highly responsive to polysaccharide antigens and with a clear surface phenotype, can be differentiated. These cells, which are sometimes named *MZ-like* or *unswitched memory*, are not restricted to the human spleen but are found circulating in the peripheral blood, as well as in the lymph nodes, tonsils, and Peyer's patches.^{46,47} They are defined as IgM+, IgD+, CD27+, CD21+, and CD1c+.⁴⁷

Given that these cells possess the “memory” marker CD27, it has been suggested that they have experienced antigenic exposure; however, the presence of MZ-like B cells in subjects with X-linked agammaglobulinemia (a CD40L deficiency) suggests that even if antigen exposure has occurred, T cell help has not.

Interestingly, MZ-like B cells, although already present at birth, do not seem to be fully functional at that time; infants up to age 2 are particularly susceptible to infections by capsulated bacteria. This might be due to the functional immaturity of the cells or to the lack of development of the antigen-trapping microstructure.

B1 Cells

In mice, B1 cells represent a minor population of B cells that reside predominantly in the pleural and peritoneal cavities. They are named B1 because it is assumed that

is the first population of B cells to develop during intra-uterine life.

Functionally, B1 cells have been characterized as self-renewing cells that possess a limited BCR repertoire and respond with low affinity to a broad array of antigens, mainly phospholipids and carbohydrate structures in the bacterial cell wall. Despite their low numbers, these cells secrete most of the natural antibodies of the organism (antibodies that appear without evidence of previous immunization) and are assumed to be the precursors of most of the plasma cells that are home to the intestinal *lamina propria*. Phenotypically, these cells are defined as IgM^{high} and IgD^{low}. About 70% of them express the marker CD5.

In humans, the definition of B1 cells is still unresolved. The CD5 marker has been used extensively as a surrogate marker for B1 cells with mixed success, given that activated human B cells also upregulate the expression of CD5.⁴⁸

SITES OF B CELL HOMING AND ACTIVATION

After the immature B cell stage, B cells home to secondary lymphoid organs, which contain the microenvironment and architecture necessary for the retention and activation of B cells. These organs include the spleen and lymph nodes, as well as lymphoid structures in mucosal tissue (e.g., Peyer's patches, appendix, tonsils). The secondary lymphoid tissue is adapted to trap circulating antigen and expose the B cells to it and to provide interactions with T cells and other co-stimulatory cells. Peripheral lymphoid tissue contains

specialized antigen-presenting cells known as *dendritic cells*. In the Peyer's patches of the intestines, foreign antigen is taken up in specialized epithelial cells known as *M cells*. Even though peripheral lymphoid tissues vary in structure and cellular organization, they all possess antigen-presenting cells and B cell-containing follicles surrounded by T cell-rich zones.⁴⁹ As explained in the following section, antigen, T cells, and dendritic cells are required for B cell activation and differentiation into Ig-secreting plasma cells or memory B cells.

B1 cells typically home to the peritoneal and pleural cavities and, to a lesser extent, the spleen. Naïve B cells enter the peripheral circulation by passing through the endothelial lining of the sinusoids of secondary lymphoid tissue and recirculate throughout the follicles of secondary lymphoid tissues. Because naïve B cells require antigen-specific T cell help for activation, the localization of this subset near a T cell zone facilitates chance encounters between antigen-specific B cells and cognate T cells. MZ-like cells respond to antigen without cognate T cell help and in mice are well positioned to capture blood-borne antigens owing to interactions between adhesion molecules and chemokine receptors expressed in part by specialized macrophages within the marginal zone that sequester MZ B cells within the marginal sinuses.

Circulation and Homing

The entry, retention, and recirculation of B cells through secondary lymphoid organs depend on both adhesion molecules and chemokine receptors.^{50,51} First, expression of LFA-1 and VLA-4 is required for entry into the lymphoid tissue. Then the chemokine receptors CXCR5 and CCR7 direct localization within the tissue. The CXCR5 molecule is expressed on all mature B cells and mediates B cell migration to follicles in response to the chemokine CXCL13, which is produced by follicular stromal cells. These cells, in turn, are regulated by lymphotoxin- α made by B cells. In the follicle, the B cells scan for antigen, making contact with potential antigen-bearing cells such as follicular dendritic cells (FDC), subcapsular macrophages, and dendritic cells. If the B cell does not encounter a cognate antigen, it will exit the lymphoid organ through the efferent lymphatics in response to the molecule sphingosine-1-phosphate (S1P). Neutralization of S1P leads to sequestration of B cells in lymphoid organs.⁵²

On antigenic encounter the B cells are retained in the lymphoid organ due to the upregulation of CCR7. The ligands for CCR7 (CCL19 and CCL21) mediate the organization of the T cell zone and attract antigen-activated B cells to this area, where cognate T cell–B cell interactions occur.

In contrast, it is assumed that MZ-like B cells respond to antigen without the help of cognate T cells. In mice, MZ B cells are present exclusively in the spleen and do not recirculate; in humans they are found in the spleen and tonsils, as well as in blood. MZ B cells localize to the outer layers of the follicles, making them among the first cells to encounter blood-borne antigens.

The interplay of chemokine expression and the induction of chemokine receptors play an important role in the germinal center response. The chemokine CXCL12

retains centroblasts in the dark zone during the process of somatic hypermutation and isotype class switching. CXCL13 regulates migration to the light zone, where survival and selection events are mediated by interactions with CXCR5-expressing follicular helper T cells and FDCs.⁵³ Later, CXCL12 promotes the migration of plasmablasts to the bone marrow, where they undergo further development into long-lived plasma cells.

Mucosa-Associated Compartments

Within the mucosal tissue, the sites of induction of immune responses are distinct from the site where the effector cells reside. There are two main sites for the induction of an immune response. The first is the mucosa-associated lymphoid tissue (MALT) that includes Peyer's patches, nasopharynx-associated tissue, and isolated lymphoid follicles, where exogenous antigen is displayed by specialized M cells that transport antigen to the follicle. The second site of induction includes mucosa-draining lymphoid nodes such as the mesenteric and cervical lymph nodes.⁵³

B cells reach these sites through the systemic circulation. Once they are stimulated by antigen and induced to differentiate, they home to the effector sites in the intestinal and respiratory *lamina propria*, where they differentiate into plasma cells and produce antibody mainly of the IgA isotype. An interesting characteristic of the plasma cells induced in the mucosal compartments is their selective homing to mucosal effector sites. Nasal activation leads to IgA-secreting cells with high levels of CCR10 and $\alpha 4\beta 1$ -integrins that home to the respiratory and genitourinary tracts in response to their ligands, CCL28 and VCAM-1. Migration to the intestinal lamina propria, in contrast, seems to be dependent on orally induced activation and subsequent expression on B cells of the chemokine receptor CCR9 and integrins that bind to CCL25 and MADCAM1/VCAM-1, respectively.⁵⁴

B CELL ACTIVATION AND DIFFERENTIATION

Engagement of surface Ig by antigen triggers a series of cellular events that regulate B cell proliferation and differentiation. Receptor cross-linking leads to relocation of the BCR to microdomains known as *lipid rafts*, which leads to the rapid activation of proximal mediators of the BCR signal transduction pathway.⁵⁵ This results in the activation of second messengers such as phospholipase C, phosphatidylinositol 3-kinase, and Ras pathways. Induction of these pathways ultimately transmits signals to the nucleus, initiating new gene expression. Depending on the type of signal delivered and the stage of maturation of the B cell, B cells can undergo either differentiation into memory B cells and plasma cells, or apoptosis. Along with surface Ig, several other membrane receptors modulate antigen-induced signal transduction.

B CELL RECEPTOR SIGNALING

B cell activation is triggered by the binding of specific antigen to the BCR. The end result of this process will

depend on the characteristics of the antigen, the B cell subpopulation activated, and the co-stimulatory signals provided by the antigen itself, T cells, and the microenvironment.

The BCR complex is composed of surface Ig, noncovalently bound to a dimer formed by the molecules Ig α and Ig β . The surface Ig on the naïve B cell includes both IgM and IgD. The role of surface Ig is to recognize foreign antigen; the Ig α and Ig β molecules transduce the signal through a particular amino acid sequence known as an *immunoreceptor tyrosine-based activation motif* (ITAM). This sequence contains two tyrosine residues that can be phosphorylated on activation. After phosphorylation, the ITAM acts as a docking site to recruit other signaling molecules.

In resting B cells, the BCRs are disorganized in the cell membrane, but after BCR cross-linking, they aggregate and translocate to specific regions of the cell membrane named *lipid rafts*.⁵⁵ The signal transduction events that occur after BCR cross-linking are mediated by the subsequent recruitment and activation of intracellular kinases including Lyn, Fyn, Btk, and Syk. The most proximal event following BCR cross-linking is the activation of Lyn, which results in the activation of the phosphatase CD45. CD54 removes the inhibitory phosphates on the ITAMs of Ig α and Ig β , and the activation of Lyn leads to the activation of Syk and Btk.⁵⁶ There is evidence that ligation of CD19, an activating co-receptor of the BCR, leads to recruitment and activation of Vav, phosphatidylinositol 3-kinase, Fyn, Lyn, and Lck.⁵⁷ Subsequently, the tyrosine kinases Syk and Btk are activated by tyrosine phosphorylation. The phosphorylation of Syk triggers the activation of phospholipase C, phosphatidylinositol 3-kinase, and Ras pathways. The activation of Syk appears to be absolutely critical for BCR-mediated signal transduction because Syk-deficient cell lines exhibit a loss of BCR-induced signaling. Btk also appears to be required for the activation of second messenger pathways. In some patients with X-linked agammaglobulinemia, a mutation in the Btk gene results in impaired BCR signaling at the pre-B cell stage.⁵⁶ As a consequence, these patients have a greatly reduced number of mature B cells and generate poor antibody responses. In mice, however, a mutation in Btk leads to a disease known as *X-linked immunodeficiency*. B cell development is impaired at the transitional T2 stage, and B cells that do go on to maturity are unable to respond to certain T cell-independent antigens.

Following recruitment and activation of the intracellular kinases, downstream pathways are initiated. Btk, Syk, and the adapter molecule BLNK are required for the activation of phospholipase C gamma. This leads to breakdown of phosphatidylinositol 4-phosphate to DAG and IP3 to trigger calcium release from intracellular stores and the subsequent translocation of nuclear factor of activated T cells (NFAT) to the nucleus. In addition, Btk activates Ras, which leads to nuclear translocation of the transcription factor activator protein-1 (AP-1). BCR cross-linking also activates MAP kinases.

Induction of these pathways ultimately transmits signals to the nucleus, where signals are integrated to regulate gene expression. The main transcriptional activator related to B cell activation is NF κ B, a family of transcriptional factors consisting of homodimers or heterodimers of different

subunits (Figure 14-5). NF κ B regulates cellular processes leading to activation, differentiation into memory B cells, and plasma cells or apoptosis.

Surface Co-receptors and Intracellular Regulators

Along with surface Ig, many molecules can modulate BCR signal transduction, either enhancing or diminishing the signal transduced by antigen. These include, but are not limited to, the B cell co-receptor complex (CD19/CD21/CD81/Leu-13), CD45, SHP-1, SHP-2, SHIP, CD22, Fc γ RIIB1, CD5, CD72, PIR-B, and PD-1 (see Figure 14-5). The integration of all these signals sets the threshold for activation of the BCR signal.

The main positive regulator of B cell activation is the B cell co-receptor complex, composed of CD19, CD21, CD81, and an interferon-inducible molecule called *Leu-13*.⁵⁸ After antigen cross-linking of surface Ig, specific tyrosine residues contained within the CD19 cytoplasmic domain rapidly become phosphorylated. Although the natural ligand for CD19 is not known, in vitro studies have demonstrated that ligation of CD19 with anti-CD19 antibody lowers the threshold required for BCR-mediated B cell activation and enhances the proliferative effect of anti-IgM treatment on B cells.⁵⁹ A role for CD19 in B cell activation has been clearly defined in mice that either lack or overexpress CD19.⁶⁰ The CD19 molecule is required for T cell-independent and T cell-dependent B cell responses and for germinal center formation. The CD21 molecule serves as a receptor for cleavage fragments of the C3 component of complement. Cross-linking of the BCR and CD21 with complement-coated antigen trigger has been proposed to trigger the activation of the cytoplasmic tail of CD19. Mice deficient in CD21 also have impaired responses to T cell-dependent and T cell-independent antigens and a defect in germinal center formation.⁶¹ The functions of the remaining two components of the B cell co-receptor complex, CD81 and Leu-13, have not been characterized, although it has been suggested that these molecules may mediate homotypic cell adhesion.

In contrast, CD22 that also associates with the BCR is primarily a negative regulator of BCR activation. Although CD22 contains an ITAM motif and is able to recruit Src tyrosine kinases to its cytoplasmic domain,⁶² it also contains a specific motif known as the *immunoreceptor tyrosine-based inhibition motif* (ITIM). Similar to the ITAM, the ITIM contains a critical tyrosine residue. After activation of Lyn, it is believed that the ITIM of CD22 is phosphorylated by Lyn, leading to the recruitment of intracellular phosphatases such as SHP-1 that downregulate the activation cascade.⁶³

Fc γ RIIB

Simultaneous ligation of both the BCR and Fc γ RIIB1 sends an inhibitory signal to diminish antigen activation of naïve and memory B cells. This inhibitory signal is activated by the presence of immune complexes and provides a negative feedback mechanism to attenuate an antigen-induced antibody response. After co-ligation of Fc γ RIIB1 and the BCR,

Figure 14-5 Molecules that regulate the activation state of B cells. Co-ligation of surface immunoglobulin results in tyrosine phosphorylation at specific tyrosine residues present in the immunoreceptor tyrosine activation motif (ITAM) of Ig α and Ig β cytoplasmic domains. This occurs after the removal of the inhibitory tyrosine residues of the B cell receptor (BCR)-associated cytoplasmic kinases such as Blk, Fyn, and Lyn, which is mediated by CD45. The phosphorylated ITAMs recruit and activate the Syk and Btk kinases, which in turn activate a series of second messenger pathways (PLC, PKC, and Ras) that result in the upregulation of genes required for B cell activation and survival. Co-ligation of the pre-BCR complex (CD19, CD21, CD81, and Leu-13) results in phosphorylation of tyrosine residues residing in the cytoplasmic domain of CD19. Cytoplasmic kinases including Vav, Fyn, and Lyn become activated and enhance the signaling mediated by the BCR. Following the activation of distal mediators of BCR signaling such as PLC, PKC, and Ras, molecules of the MAPK pathway become activated and translocate to the nucleus to regulate gene expression. Signals mediated by CD22, PIR-B, CD72, PD-1, Fc γ RIIB1, and CD5 deliver negative signals that block the activation of distal molecules. Following phosphorylation of the immunoreceptor tyrosine inhibition motif (ITIM), present in the cytoplasmic tail of these molecules, the phosphatases SHP-1, SHP-2, and SHIP are recruited and activated.

it is believed that Lyn phosphorylates Fc γ RIIB1.⁶⁴ SHIP then associates with the Fc γ RIIB1 and mediates the dephosphorylation of CD19, thereby terminating BCR signaling.

CD5

The role of CD5 in B1a cell function is not well understood. After BCR cross-linking, CD5 is thought to mediate signals that induce apoptosis and block proliferation.⁶⁵ Cross-linking of CD5 with an anti-CD5 monoclonal antibody results in apoptosis. There is some evidence that CD5 recruits the inhibitory phosphatase SHP-1 to its cytoplasmic domain. However, unlike CD22 and Fc γ RIIB1, CD5 does not contain a strong ITIM consensus sequence and may recruit SHP-1 indirectly.⁶⁶ The ligand-binding region of CD5 remains to be elucidated, but recent evidence suggests that CD5 may be a ligand for another negative regulator of BCR signaling, CD72.

CD72

CD72 is a transmembrane receptor that is expressed as a homodimer. The cytoplasmic tail of CD72 contains ITIMs. Mice with a targeted disruption of the CD72 gene reveal

that CD72 plays a negative role in B cell activation, presumably through recruitment of SHP-1. The B cell of CD72-deficient mice is similar to that of viable moth-eaten mice with expansion of B1 cells and B cells that are hyper-responsive to BCR cross-linking and are more resistant to BCR-mediated apoptosis.⁶⁷ There are several putative ligands for CD72 including CD5 and CD100.

PIR

Paired Ig-like receptor (PIR)-A and PIR-B are expressed in a pair-wise fashion, as the names imply. These receptors are believed to have opposing functions, with PIR-A inducing an activation signal and PIR-B inducing an inhibition signal. The ligands for PIR-A and PIR-B remain to be elucidated. Although little is known about the role of PIR-A in B cell activation, recent data demonstrate that PIR-B plays a role in downregulating B cell responses. The cytoplasmic tail of PIR-B possesses several ITIMs that recruit inhibitory phosphatases. Mice that harbor a targeted disruption of the PIR-B gene exhibit a phenotype similar to mice that are deficient in the other ITIM-bearing inhibitory receptors such as an expansion of B1 cells and B cell hyperresponsiveness.⁶⁸

PD-1

PD-1 is an inhibitory molecule expressed predominantly on activated B and T cells. The ligand-binding domain binds PD-1L, and the cytoplasmic tail of PD-1 contains ITIMs that recruit SHP-2 to attenuate BCR signals. The B cells of PD-1-deficient mice are hyperresponsive to BCR signaling, and these mice display an augmented response to T cell-independent type II antigens. On certain genetic backgrounds, PD-1 deficiency leads to an autoimmune phenotype.⁶⁹

Protein Tyrosine Phosphatases

In general, intracellular signaling is regulated by a balance of phosphorylation and dephosphorylation. Protein tyrosine phosphatases (PTP) play a major role; among these, SHP-1, a tyrosine phosphatase, is a potent negative regulator of BCR signaling. SHP-1 is found in association with transmembrane proteins such as CD22, FcγRIIB1, CD5, CD72, and PIR-B. SHP-1 antagonizes BCR signaling by inactivating tyrosine kinases associated with signaling.⁶⁶ The function of SHP-1 has been extensively studied in mice that bear a naturally occurring mutation in the SHP-1 gene. Mice with this genetic defect are known as moth-eaten mice because of the appearance of their fur. These mice have a decreased number of conventional B cells and an expansion of B1 cells, producing autoreactive IgM antibodies.⁷⁰ This defect in B cell regulation underscores the importance of SHP-1 in limiting the extent of BCR signaling. In contrast, the intracellular tyrosine phosphatase SHP-2, although structurally similar to SHP-1, seems to play a positive regulatory role, as it augments ERK responses.⁷¹ The important role played by PTP in disease is demonstrated by the discovery that a single mutation in the PTPN22, a protein that regulates Src family kinases, augments the risk of multiple autoimmune diseases.⁷²

Another important regulator, SHIP is an inositol phosphatase that inhibits B cell activation by hydrolyzing the 5' phosphate form of phosphatidylinositol 3,4,5-triphosphate, a critical component of numerous signaling pathways. Similar to SHP-1 and SHP-2, SHIP is recruited to an ITIM on FcγRIIB following BCR cross-linking. Mice deficient in SHIP display splenomegaly and elevated levels of serum antibody.⁷³

Signal Transduction in Immature versus Mature B Cells

An important event in BCR signaling is the recruitment of signaling components to lipid rafts, which are lipid-rich microdomains of the membrane that serve to bring together requisite signal molecules to facilitate integrated functions in three-dimension. In the resting state, the BCR is excluded from lipid rafts, but following antigen engagement, the BCR translocates into rafts and the BCR signaling cascade ensues because of the clustering of signaling components. In addition to activating signals, however, inhibitory components also localize to lipid rafts. As discussed later, BCR ligation mediates negative selection during the immature and transitional B cell stages and B cell activation during the mature B cell stage. The reason for these two distinct outcomes is not clear because the same signal components are present; however, differences in membrane cholesterol limit recruitment of the BCR to lipid rafts in immature B cells.⁷⁴ There is also evidence that the signal strength and duration and stage-specific expression patterns of signaling elements differ between immature and mature B cells.⁷⁵

B Cell Activation

B cells develop without bias for a particular antigenic specificity, ensuring that a diverse repertoire of different Ig molecules is produced. Despite the expression of antiapoptotic molecules such as Bcl-2, naïve B cells are short-lived unless they are activated by antigen and accessory cells such as dendritic cells and T cells. Antigen-activated B cells undergo clonal expansion; B cells that do not interact with antigen are destined to undergo programmed cell death in a matter of days or weeks. The B1 and B2 cell subsets are regulated by different activation mechanisms and are involved in different immune responses (Table 14-3).

B1 Cell Activation

B1 cells present in the pleural and peritoneal cavities respond to T cell-independent antigens. There are two classes of T cell-independent antigens: type I, which includes lipopolysaccharide, and type II, which includes large multivalent antigens with repetitive epitopes, often

Table 14-3 Markers of Human Mature B Cell Subsets

Characteristic	Naive	Unswitched Memory	Switched Memory	B1
Surface IgM	High	High	Low	High
Surface IgD	Low	Low	High	Low
CD5	+	—	—	—/+
CD21	—	—	+	++

found on the surface of bacteria. T cell–independent antigens can directly activate B cells, resulting in the secretion of antibody. Soluble factors such as IL-5 and IL-10 also appear to be involved in the maintenance and activation of B1 cells.

B1 cells do not require interaction with antigen-specific T cells. However, activated T cells and macrophages may augment B1 cell activation, enhance Ig production, and influence isotype class switching such that B1 cells may also produce IgA and IgG.

Marginal Zone B Cell Activation

If antigen reaches the lymphoid organ from the blood and is recognized by an MZ-like B cell, B cell activation is independent of T cell help. The absence of a requirement for T cell help is a function of the highly repetitive structures of MZ B cell antigens that causes BCR cross-linking. MZ B cells are situated in the marginal sinuses, where specialized macrophages trap and remove antigen from the circulation. Soluble factors such as BAFF and T cell–derived cytokines are important for MZ B cell activation. Following activation by antigen, MZ B cells differentiate rapidly into short-lived antibody-secreting plasma cells. MZ B cells secrete predominantly IgM and, to a lesser extent, IgG antibodies. These antibodies display low to intermediate affinity, and there is no induction of affinity maturation events.

Naïve B Cell Activation

Engagement of the BCR by antigen signals the B cells to engulf the antigen, process it intracellularly, and express peptide fragments bound to MHC class II molecules on its surface. After the expression of peptide fragments bound to MHC class II molecules, antigen-activated B cells present peptide to primed helper T cells. B cells and T cells interact through T cell receptor recognition of a peptide-MHC complex on the B cell and through engagement of co-stimulatory molecules B7 and CD40 on the B cell by CD28 and CD40L, respectively, on T cells (Figure 14-6). The B7 molecule is not constitutively expressed on B cells but is induced after antigen uptake by B cells. B cell activation during a T cell–dependent immune response also depends on engagement of the CD40 receptor expressed on B cells with the CD40 ligand (CD40L) expressed on T cells.⁷⁶ The importance of signal transduction events mediated by CD40-CD40L engagement is evident from studies of patients with X-linked hyper-IgM syndrome, an immunodeficiency disease resulting from a defect in CD40L. These individuals do not mount strong immune responses to T cell–dependent antigens; they have high concentrations of circulating IgM but only trace amounts of IgG and no affinity maturation of the antibody response. Helper T cells secrete cytokines such as IL-2, IL-3, IL-4, IL-5, IL-10, IL-17, and IFN- γ and provide co-stimulatory signals that are important for B cell maturation and differentiation.⁷⁷

On encountering antigen, a naïve B cell with high affinity for the antigen will activate and differentiate to a plasma cell that will secrete IgM or IgG antibodies without somatic mutations. If the activated B cell, however, harbors a receptor with low to intermediate affinity for antigen, the cell

Figure 14-6 B cells as antigen-presenting cells. Antigen bound to surface immunoglobulin on naïve B cells triggers endocytosis and intracellular processing of the antigen. B cells engage antigen-specific helper T (T_H) cells through the recognition of foreign peptide by the T cell receptor (TCR) and through the binding of a conserved region of the MHC II molecule by CD4. Along with antigen binding, co-ligation of CD40 and B7 (expressed on B cells) with CD40L and CD28 (expressed on T cells) provides critical co-stimulatory signals and the secretion of cytokines required for B cell activation.

will migrate first to the T cell area of the follicle and will begin the process of creating a germinal center.⁷⁸

Germinal Centers

As B cells progress to form germinal centers (GCs), they interact with cognate T cells that are a specialized subpopulation of helper cells known as *T follicular helpers* (T_{FH}). These T_{FH} cells express CXCR5 and, therefore, can migrate to the B cell areas, where, along with the activated B cells, they form discrete structures in the primary follicles, known as *germinal centers*. These are the sites where class switch recombination (CSR), affinity maturation through somatic hypermutation (SHM), and differentiation into memory B cells or long-lived plasma cells occur.

Germinal centers can be subdivided into separate regions where the different stages of B cell differentiation take place (Figure 14-7). The dark zone is the initial site of rapid proliferation, and B cells within the dark zone are called *centroblasts*. They are derived from a relatively small number of antigen-activated B cells (Table 14-4). Expression of the antiapoptotic Bcl-2 protein is low in these cells, whereas expression of the proapoptotic Fas protein is upregulated. Low levels of Bcl-2 expression render developing B cells sensitive to apoptosis, but these cells can be rescued by antigen and CD40-CD40L interactions provided by antigen-specific helper T cells. When these cells migrate to the light zone, they are termed *centrocytes* and encounter a dense network of follicular dendritic cells (FDCs) and T_{FH} . B cells that do not express moderate to high affinity BCRs are excluded from the light zone.

The process of somatic mutation is activated during the centroblast stage. During this process, a nucleotide base-pair

Figure 14-7 B cell maturation in germinal centers. Following exposure to antigen, B cells in the primary follicles form germinal centers or migrate to previously formed germinal centers. Centroblasts located in the dark zone undergo proliferation and acquire somatic mutations. A small number of proliferating centroblasts can give rise to a larger number of centrocytes present in the basal light zone. As these cells pass through a dense network of follicular dendritic cells (FDCs) and helper T cells (T_H), centrocytes bearing surface immunoglobulin receptors with high affinity for antigen undergo positive selection. Centrocytes in the apical light zone are nondividing cells that undergo differentiation into memory B cells or plasma cells. It has been suggested that centrocytes may return to the dark zone, where additional somatic mutations may be acquired. Resting B cells that are not activated by antigen are pushed aside to form the follicular mantle zone.

change is introduced in the DNA sequence of Ig genes, at approximately 10^{-3} per base pair per cell division, in the variable region of H- and L-chain genes. The mechanism for *somatic hypermutation* (SHM) is complex and requires specific hotspot sequences and the enzyme Activation-induced Cytidine Deaminase (AID).⁷⁹ The process of SHM is responsible for the affinity maturation of the antibody response. B cell clones that express surface Ig with an increased affinity for antigen are selectively expanded

during the affinity maturation process, whereas B cells that express somatically mutated Igs with low affinity for antigen or novel binding to self-antigens are targeted for apoptosis or inactivation. The importance of somatic mutation and affinity maturation during an immune response is underscored by the fact that patients with mutations in the AID gene are immunocompromised.

AID is critical for not only somatic hypermutation but also CSR. Although expression of IgM and IgD in B cells occurs through alternative splicing of a long transcript that contains coding regions for both the μ and δ -chain, expression of any other Ig isotype requires the excision of all the heavy chain genes between the recombined VDJ region and the isotype to be expressed. Isotype switching requires pre-activation of the particular heavy chain locus to be involved in the recombination event; this is controlled by the cytokine milieu in which the cell is activated. For both processes, AID induces the deamination of cytidine, creating dU:dG pairs (instead of dC:dG) that activate the cellular DNA repair machinery and ultimately create circumstances that favor both CSR and SHM. For CSR, CD40-CD40L interactions and cytokines are also required.

As centroblasts become centrocytes, they require survival signals from FDCs to overcome their low level of Bcl-2 expression and high level for Fas expression. FDCs are stromal-derived cells that trap antigen by collecting antigen-antibody complexes bound to Fc γ R in bodies known as *icosomes* (immune complex-coated bodies) on the cell surface. Icosomes deliver an antigen-specific signal to B cells through the BCR (Figure 14-8). Centrocytes with specificity for antigen on FDCs are saved from apoptosis by upregulation of the Bcl-2 molecule. Engagement of the complement receptors CR1 and CR2 (CD21 and CD35, respectively) on B cells by components of the C3 complement protein (iC3b, C3dg, and C3d) bound to FDCs may mediate a secondary co-stimulatory signal.⁸⁰ If centrocytes do not receive these positive selection signals, they rapidly die through a Fas-dependent pathway. Should they receive survival signals, they continue to differentiate into memory B cells or plasma cells.

Ectopic Lymphoid Structures

Despite being the prototypical structure for the induction of humoral immune responses, germinal centers are not found exclusively in lymphoid tissue. Ectopic lymphoid

*Bcl-2 is expressed in centrocytes only after interaction with follicular dendritic cells.

Figure 14-8 Engagement of B cells with follicular dendritic cells. Interaction between follicular dendritic cells (FDCs) and B cells results in signals that mediate the positive selection of B cells in germinal centers (GCs). Antigen-antibody complexes trapped on the FDC surface deliver a signal to the B cell receptor (BCR). A second signal is delivered by the binding of CD21 on B cells to C3 complement components on the surface of FDCs.

structures (eLS) with GC-like characteristics are present in sites of chronic inflammation such as the synovium in rheumatoid arthritis, pancreatic islands in type 1 diabetes, and salivary glands of Sjögren's syndrome patients.⁸¹

These GC-like structures seem to develop as a consequence of chronic inflammation, which leads to the release of soluble mediators such as the chemokines CCL21 and CXCL12,⁸² which recruit lymphocytes. These cells, once activated, secrete cytokines such as lymphotoxin that act in a paracrine manner and contribute to the organization of a GC-like structure that includes a dark and light zone with local induction of AID. In contrast to the GC of the secondary lymphoid organs, these structures are not encapsulated. The B cells in these structures, therefore, are continuously exposed both to the local antigens that might be absent from the lymphoid organs⁸³ and to the inflammatory microenvironment that may facilitate bypass of the regulatory points in B cell differentiation, hence contributing to a potential autoimmune bias in these sites. Although there is no evidence that these structures are the underlying cause of any disease, in some diseases they may contribute to tissue pathology and augment the pool of autoreactive plasma and memory cells. Not all ectopic lymphoid foci share characteristics with the GC. Which structures are more damaging to tissue is not known.

REPertoire POST ANTIGEN ACTIVATION

The hallmarks of the germinal center process, affinity maturation and class switch recombination, find their functional expression in the two cell types to which B cells differentiate in the late stages of the germinal center: memory B cells and plasma cells.

Memory B Cells

Postgerminal center memory B cells express Ig genes that have undergone isotype class switching and possess somatic

mutations, and in humans they are distinguished by the presence of the marker CD27. The CD40-CD40L interaction contributes to directing GC B cells to mature into long-lived memory B cells. The exact life span of memory B cells is unknown. It has been postulated that these B cells either persist throughout the lifetime of the host⁸⁴ or are renewed constantly through either nonspecific⁸⁵ or antigen-specific stimulation.⁸⁶

Memory B cells circulate throughout the body in a quiescent state until specific antigen is re-encountered and triggers a potent secondary immune response. Memory cells respond to antigen much faster, require lower amounts of antigen, and can even be induced in its absence by soluble mediators such as IL-2 or IL-15, in part because the BCR is already localized to lipid rafts. Subsequently, just like naïve B cells, memory B cells ingest antigen and express peptide-MHC class II fragments. After antigen presentation of peptide to helper T cells, memory B cells undergo expansion and may differentiate to plasma cells.

Plasma Cells

The B cell differentiation cascade ends with the generation of a plasma cell. At the molecular level, the differentiation program is directed by the transcriptional repressor known as *B lymphocyte-induced maturation transcription factor* (Blimp-1).⁸⁷ Blimp-1 induces a program in which plasma cells lose expression of several markers, as they no longer express surface Ig, MHC molecules, or CD20. They initiate increased protein synthesis and secretion and consequently exhibit a large cytoplasm with a well-developed endoplasmic reticulum, devoted to antibody production.

B cells differentiating into plasma cells exit the lymphoid follicles and migrate to extrafollicular regions of secondary lymphoid tissue or to the bone marrow, where the final stage of plasma cell maturation occurs. B cells in the GC are induced to become plasma cells by IL-5, IL-6, and IL-21. Plasma cells have a variable life span that may be days for short-lived plasma cells that originate extrafollicular responses to years for long-lived plasma cells that arise from the GC response and home to the bone marrow.⁸⁸

The longevity of plasma cells in the bone marrow depends on the presence of a niche that provides the survival factors cxcl12, APRIL, and TNF. Cross-linking the $\text{Fc}\gamma\text{RIIb}$ expressed by the plasma cells induces apoptosis, a phenomenon that has been credited with pruning the plasma cell repertoire.⁶

Trafficking of Postimmune Cells

Both memory and plasma cells express CXCR4 that directs homing to the bone marrow but also allows localization in lymphoid tissues. Therefore CXCR4-expressing plasma cells can be found surrounding the GC or B cell follicles.⁸⁹ A subset of memory cells expresses CXCR3 and therefore migrates toward inflammatory chemokines such as CXCL9 and CXCL10.⁹⁰

ANTIGEN-INDEPENDENT ACTIVATION

Although it is a central paradigm that B cells require cognate antigen for activation, it has also been known

for years that infections induce an antibody response where only a fraction of the responding B cells are specific for microbial antigen. This phenomenon, known as *polyclonal activation*, is induced through several mediators such as superantigen, cytokines, or noncognate T cell co-stimulation and to the production of self-reactive antibodies.

B cell superantigens include the *Staphylococcus aureus* protein A (SpA), the protein gp120 of HIV-1, and the erythrocyte membrane protein 1 of *Plasmodium falciparum*. These proteins share the ability to bypass the need to be recognized in the antibody-binding site and bind instead to framework regions common to Ig gene families. They can therefore activate multiple clones; for example, SpA recognizes Igs of the V_H3 family that comprises up to 50% of the IgM repertoire.⁹¹ Although the activation of multiple B cell clones by an organism might be seen as an advantage for the host, polyclonal activation leads to an extrafollicular response that, after a transient hyperglobulinemia, exhausts the B cell pool, leaving a vulnerable organism.

Noncognate activation of B cells clearly occurs in memory B cells that are easily activated by the presence of soluble mediators such as IL-2, IL-15, or CpG (see Memory B Cells).⁸⁵ In chronic infections, polyclonal activation seems to be a consequence of two nonmutually exclusive mechanisms. The simpler one is bystander activation of noncognate B cells by inflammatory cytokines. The second is CD4+ T cell-mediated co-stimulation. Noncognate B cell activation carries the intrinsic risk of activating self-reactive B cells, as is observed in both experimental and natural infections.⁹²

Mucosal T-Independent Class Switch Recombination (CSR)

In the mucosa, IgA specific to commensal bacteria is induced through machinery that is T cell independent and occurs outside of organized lymphoid tissue.⁹³ Because this phenomenon is independent of T cells, other interactions must provide the required signals for CSR. One of the candidate molecules is BAFF (BlyS) that is expressed by dendritic cells in mucosal tissue. BAFF has been shown to induce CSR in B cells in the presence of IL-10 or TGF- β , both of which are present in the mucosal microenvironment.⁹⁴

REPertoire SELECTION

The ability to discriminate between foreign and self-antigens is as important as the capacity to mount a protective immune response. Any molecule derived from the intracellular or extracellular components of the host can be considered self-antigen; the censoring of the responses against these antigens occurs throughout B cell maturation and includes multiple mechanisms in the B cells themselves and in cells that cooperate in their activation and differentiation.

Tolerance

The discrimination between self and foreign structures is achieved through signals provided by the BCR, co-receptors,

inflammatory mediators, and metabolic by-products that are integrated by the cell according to its developmental stage. There is no absolute recognition of self. BCR cross-linking during development or in absence of co-stimulatory signals activates tolerance mechanisms in immature and transitional B cells. The same mechanisms that induce tolerance to self-antigen can induce tolerance to pathogens, and because some autoantigens are sequestered in sites of immune privilege, cells specific to them are not subject to tolerance mechanisms.

The tolerance mechanism activated depends on the stage of the B cell and the strength of the BCR signal delivered by antigen. The strength of the signal depends on the degree of cross-linking of the BCR, which in turns depends on the concentration of self-antigen and the affinity of the antibody for self-antigen. With little receptor cross-linking, because of low antigen concentration or low affinity for antigen, there is no BCR signaling, and the autoreactive B cell is not tolerized. Three mechanisms mediate tolerance induction: receptor editing, anergy, and deletion. When mechanisms that regulate autoreactive B cells fail, the breakdown of self-tolerance can lead to the development of autoimmune disease.

During B cell development, autoreactive B cells are generated in the bone marrow after V(D)J rearrangement and expression of surface Ig on immature B cells. Because of the vast number of different antibody molecules that can be formed through the random recombination of H- and L-chain variable region genes and the random association of H and L chains, all individuals generate autoreactive B cells. The process that prevents the maturation of naïve autoreactive B cells is known as *central tolerance*, and it occurs with such efficiency that despite the fact that more than 75% of immature B cells bear receptors with some degree of autoreactivity, less than 20% of naïve B cells do so.⁹⁵

Receptor Editing

A high degree of cross-linking of the BCR during development results in a process known as *receptor editing*. This process involves a secondary gene rearrangement of the heavy chain or light chain genes. Receptor editing requires reactivation of the recombination machinery and re-expression of RAG-1/2. When successful, receptor editing produces a BCR receptor with low or no affinity to the antigens present in its environment, and the cell is allowed to continue its development. RAG-1/2 can be seen in some cells in the germinal center or extrafollicular region as well, and some authors have interpreted this as evidence that receptor editing also occurs later in B cell development.

Deletion

Extensive BCR cross-linking also leads to deletion. This was the first mechanism of tolerance described for B cells⁹⁶ and was long believed to be the main mechanism of central tolerance. However, deletion occurs only when cells are not able to decrease their autoreactivity by editing the BCR. In the periphery, deletion occurs if a B cell is extensively activated in the absence of helper T cell co-stimulation. The

cells marked for deletion are subject to apoptosis. This is a highly regulated event mediated primarily through the activation of a series of endogenous proteases. In B cells the Fas pathway and the Bcl-2 pathway play important roles in regulating apoptosis.

Fas (also known as CD95 or Apo-1), a member of the tumor necrosis factor receptor gene family, and Fas ligand are transmembrane proteins expressed on a variety of cell types. Because Fas ligand is a homotrimeric molecule, it can bind three Fas molecules. Clustering of Fas on the cell surface, which occurs when Fas molecules bind Fas ligand, activates apoptosis.⁹⁷ It appears that when B cells engage CD40L expressed on helper T cells in the absence of BCR ligation, Fas signaling induces apoptosis.^{98,99} Mutations in Fas (*lpr*) or Fas ligand (*gld*) in mice result in a systemic lupus erythematosus (SLE)-like syndrome characterized by the production of pathogenic autoantibodies and lymphadenopathy. In humans, similar mutations lead to lymphadenopathy and antierthrocyte antibodies, but anti-DNA antibodies and glomerulonephritis are not expressed in these individuals.¹⁰⁰ The Bcl-2 gene family is composed of molecules that either protect against or induce apoptosis in many cell types. Relative levels of these molecules dictate cell fate. For example, excess Bcl-2 or Bcl-XL promotes cell survival, whereas excess Bax or Bim induces cell death.¹⁰¹ Bcl-2 and Bcl-XL are upregulated at critical points during B cell development but can be easily counterbalanced on BCR cross-linking. The fact that certain mouse strains that overexpress Bcl-2 in B cells produce autoantibodies highlights the importance of apoptosis in tolerance.¹⁰²

Anergy

Anergy is a hyporesponsive state considered to be induced in immature B cells when they undergo a modest degree of BCR cross-linking. Anergic B cells downregulate surface Ig receptors and display a desensitization of the BCR, blocking activation of downstream signaling. Anergic B cells are short-lived. Goodnow and colleagues¹⁰³ performed classic studies on B cell tolerance induction in mice engineered to express an anti-hen egg lysozyme (HEL) antibody, along with soluble HEL, to act as a self-antigen. In the anti-HEL transgenic mouse model, B cells that encounter soluble, monovalent HEL are anergized. These B cells populate secondary lymphoid tissue but do not secrete anti-HEL antibody and are not recruited into B cell follicles. This phenomenon is known as *follicular exclusion*.¹⁰⁴

Although anergy implies that the cells are not activated through BCR engagement, they can be activated by non-antigen-specific T cell co-stimulation, lipopolysaccharide, or IL-4. Exposure of anergic B cells in vivo to multivalent antigen in the presence of activated helper T cells may also lead to their activation.¹⁰⁵ Consequently, it has been suggested that anergic B cells may serve as a potential source of autoantibody and may be activated in inflammatory conditions. Recently, it has been shown that B cells can be blocked from activation if they are chronically exposed to antigen and IL-6. If IL-6 is removed from the microenvironment, those chronically activated B cells will secrete antibody.

B Cells as Immune Regulators

B cells produce cytokines in response to their environment. Recently, the paracrine and autocrine role of these cytokines has become of great interest because clinical trials directed at B cells in multiple autoimmune diseases have shown improvement, which cannot be completely explained by a decrease of antibody titers. For example, it has been suggested that the therapeutic efficacy of B cell depletion reflects IL-10 secretion by transitional cells reconstituting the B cell compartment.¹⁰⁶ Recently, it has been shown that in healthy subjects, some transitional B cells secrete IL-10 in response to CD40 engagement, whereas the equivalent population in SLE patients fails to do so.¹⁰⁷

REGULATION BY SMALL MOLECULES

Beyond the classic activators and regulators, the molecules described below play a particularly important role in the biology of B cells and are highlighted given their potential as biomarkers and therapeutic agents.

Vitamin D

Vitamin D is acquired from the diet or synthesized in the skin, followed by a conversion into a biologic product in the liver and kidney. The active metabolite, 1,25-dihydroxyvitamin D₃, has been shown to decrease activation and proliferation of B cells, as well as differentiation to plasma cells. Circulating levels of vitamin D tend to be decreased in patients with autoimmune disease; whether this contributes to the disease process is not known.

Estrogens

The role of estrogens in B cell-mediated autoimmune diseases has long been suggested by the female gender predominance within autoimmune diseases. This may reflect a variety of effector mechanisms. However, estrogens have been shown to modify the B cell repertoire, allowing survival of autoreactive B cells, and to alter the peripheral compartments in mice.¹⁰⁸

Leptin

Although its first described role was as an endocrine hormone with a primary role in the control of metabolism, leptin was later shown to exhibit immune regulatory effects. For example, a murine model of experimentally induced arthritis is attenuated in leptin receptor-deficient mice.¹⁰⁹ More recently, it has been shown that leptin promotes B cell survival and proliferation, through induction of Bcl-2 and cyclin D1.¹¹⁰

B CELL-MEDIATED AUTOIMMUNITY

B cell-mediated autoimmunity is the consequence of the production of self-reactive antibodies. We have detailed multiple mechanisms operating throughout B cell maturation and differentiation that are designed to avoid autoreactivity. The failure of only one tolerance checkpoint rarely leads to autoimmune disease¹¹¹; it may, however, increase

the level of circulating autoantibodies, without clinical disease.

The generation of a B cell–mediated autoimmune disease must involve (1) the generation of B cells bearing autoreactive BCRs; (2) failure of mechanisms that in the normal event will abrogate their maturation to short- or long-lived plasma cells; and (3) tissue effects mediated by the autoantibody that leads to clinical disease.

Origin of Autoreactive B Cells

Theoretically, autoreactive cells can arise early in the repertoire from any B cell subpopulation. In mice, B1 cells that bear BCRs with low affinities but high poly-reactivity produce autoantibodies, but these autoantibodies help remove cellular debris and their absence is associated with pathogenic autoreactivity. In addition, evidence indicates that MZ B cells secrete autoantibodies. These may also provide a physiologic rather than pathologic function.

Autoreactivity in the Preimmune B Cell Repertoire

Studies of the reactivity of human B cells have shown that in the healthy peripheral B cell compartment, about 20% of the naïve B cells bear some degree of autoreactivity; however, little of those can be considered potentially pathogenic given their low affinity for autoantigen.⁹⁵ In subjects with SLE, the frequency of autoreactive cells is as high as 50% in the naïve B cell population¹¹²; the frequency is greatest when disease is active and diminishes during periods of disease quiescence,¹¹³ demonstrating that an inflammatory milieu may alter B cell selection.

Autoreactivity in the Postimmune B Cell Repertoire

It has been suggested that most of the autoreactivity in patients with autoimmune disease is derived from class-switched antibodies that display extensive somatic mutation. Back mutation to the germline sequence often leads to a loss of autoreactivity. This observation suggests that the germinal center does not possess a fail-proof mechanism to effectively purge mutated autoreactive cells, although post-GC receptor editing and deletion of autoreactive B cells has been shown to occur. The understanding of the tolerance mechanisms for autoreactive B cells that achieve autoreactivity through somatic mutation is still incomplete.

MOLECULAR TRIGGERS OF AUTOIMMUNITY

Several prevailing theories attempt to explain the activation and expansion of B cells that should normally be silenced. Autoimmunity is thought to arise by a combination of environmental factors such as infectious agents that initiate an autoimmune response and genetic defects that alter B cell regulation. Proposed models for autoimmunity include (1) cross-reactivity of foreign antigen with

self-antigen, (2) inappropriate co-stimulation, and (3) altered thresholds for BCR signaling.

Much of our understanding of the breakdown of self-tolerance and the progression of autoimmunity comes from the examination of mouse models. Autoimmune mouse models can be divided into two broad categories: induced autoimmunity and spontaneously occurring autoimmunity. Even though the progression of autoimmunity in humans is thought to be a highly complex process that involves multiple genetic and environmental factors, these animal models have provided much information about the molecular events that lead to a loss of self-tolerance.

Molecular Mimicry

One proposed model for the initiation of autoreactivity is that cross-reactive anti-self, anti-foreign B cells escape central tolerance because self-antigen is present at too low a concentration to trigger tolerance induction or because the affinity of the antibody for autoantigen is below the signaling threshold. These B cells become activated in the periphery by foreign pathogens resembling self-antigen and produce antibodies that bind both foreign and self-antigen. This cross-reactivity is known as *molecular mimicry*—this is a popular model to explain the induction of many autoimmune disorders.¹¹⁴ Once the pathogen is cleared, the autoantibody response should be terminated because antigen-specific T cell help is no longer present. In the case of autoimmune-prone individuals, it is proposed that intrinsic B cell defects prevent the downregulation of autoantibody production, even after foreign antigen clearance. Several data support molecular mimicry as a trigger for B cell–mediated autoimmunity in some instances: Antibodies to infectious agents have been identified that cross-react with self-molecules associated with specific autoimmune diseases¹¹⁵ (Table 14-5). Intriguing examples include the cross-reactivity observed between the M protein of group A *Streptococcus* and cardiac myosin in rheumatic heart disease and the cross-reactivity between *Campylobacter* and aquaporin.

Because both nonautoimmune and autoimmune-prone individuals have the capacity to generate autoantibodies, it is unlikely that cross-reactivity between foreign and

Table 14-5 Evidence for Antibody Cross-Reactivity between Foreign and Self-Antigens

Foreign Antigen	Self-Antigen

self-antigens is solely responsible for breakdown of tolerance. A plausible explanation is that foreign antigen acts as a molecular trigger to initiate an immune response to self-molecules, and a defect in the mechanism that regulates B cell activation leads to the propagation of an autoimmune response.

In general, an initial immune response is generated against a dominant set of epitopes, followed by a later response to secondary or “cryptic” epitopes, a process known as *epitope spreading*.¹¹⁶ Epitope spreading is an important aspect of a protective immune response because the ability to recognize multiple antigenic determinants increases the efficiency of the neutralization and removal of pathogens. When an autoimmune response has been triggered, epitope spreading can lead to the production of additional autoantibodies with specificity for multiple self-antigens. There are several proposed mechanisms by which epitope spreading triggers a cascade of T and B cell activation. For instance, antigen-presenting cells may present a foreign peptide that mimics a self-peptide to T cells (Figure 14-9A). Such cross-reactive T cells become activated and provide co-stimulation to autoreactive B cells that recognize self-antigen. This results in the production of autoantibodies specific for the antigen recognized by the T cell. After internalization of the self-antigen by the autoreactive B cells, the autoantigen is processed and new cryptic epitopes of the self-antigen are presented to T cells. A B cell binding to the self-antigen internalizes not only that self-antigen but also any complex of molecules that includes the self-antigen. The B cell may, therefore, present cryptic epitopes of many self-antigens and activate autoreactive T cells representing multiple auto-specificities. In the periphery, T cells are present that have not been tolerized necessarily to these (cryptic) epitopes and thus are activated by self-peptide. These activated T cells in turn help provide co-stimulation and activate other autoreactive B cells.

Alternatively, cross-reactive B cells may be activated first after exposure to foreign antigen and T cell help (Figure 14-9B). These B cells internalize self-antigen and present cryptic peptides to T cells that have not been tolerized, leading to activation of autoreactive T cells and initiation of the cascade. Thus molecular mimicry and epitope spreading could lead to the activation of T cells and B cells specific for multiple autoantigens as long as the autoantigens form a complex in vivo.

Supraoptimal B Cell Co-stimulation

It is evident that co-stimulatory signals provided by T cells play a critical role in B cell activation. Therefore inappropriate co-stimulation may lead to the propagation of an immune response directed against a self-antigen. The interaction between B7 on B cells and CD28 on T cells is crucial for the activation of antigen-specific T cells and B cells. When a genetically engineered protein that inhibits B7-CD28 interactions is administered to autoimmune mice, progression of disease is blocked.¹¹⁷ Reciprocally, autoreactive B cells present in mice that constitutively overexpress B7 are not sensitive to Fas killing and mice display high serum autoantibody titers.¹¹⁸ Overexpression of CD40 or CD40L may also activate autoreactivity. In vitro studies have demonstrated that CD40-CD40L ligation in the

presence of IL-4 activates anergic cells. It has been suggested that CD40L may be overexpressed in lymphoid cells of patients with SLE.^{119,120}

Roquin, a member of the ubiquitin ligase family, regulates the function of follicular helper T cells. Roquin belongs to a family of RING-type ubiquitin ligases involved in the post-translational regulation of gene expression and represses the expression of ICOS, a co-stimulatory molecule that plays an important role in follicular helper T cell function. These cells provide strong co-stimulation in the germinal center. Mice harboring a mutation in the roquin gene display high-affinity dsDNA antibodies owing to increased numbers of germinal center B cells and follicular helper T cells.¹²¹

Interferon regulatory factor-4 binding protein (IBP) has also been shown to regulate T cell co-stimulatory signals.¹²² IBP is a regulator of Rho GTPases and is recruited to the immunologic synapse following T cell receptor cross-linking to mediate the reorganization of the cytoskeleton. Mice deficient in IBP exhibit an autoimmune phenotype characterized by the production of dsDNA antibodies and glomerulonephritis. IBP plays an important role in the survival and effector function of memory T cells and underscores a novel role for Rho GTPases in regulating interactions between T cells and autoreactive B cells.

Toll-like receptors (TLRs) belong to a family of pattern recognition receptors that initiate innate immune responses to various components of pathogens. TLR7, which recognizes RNA, and TLR9, which recognizes unmethylated CpG-containing nucleic acid sequences, are expressed on B cells and have been implicated in autoimmunity. Numerous studies suggest that engagement of the BCR and TLR with immune complexes containing nuclear antigens triggers the activation of antinuclear B cells, implying that TLR7 and TLR9 can function to enhance the activation of autoreactive B cells under some circumstances.¹²³⁻¹²⁵

B Cell Signaling Thresholds

The effects of altering the threshold for BCR signaling have been demonstrated in several mouse models. In transgenic mice that overexpress the BCR co-receptor complex component CD19, normally anergic B cells are activated and secrete autoantibody.¹²⁶ These results suggest that a decrease in the minimal requirement for antigen engagement of the BCR can lead to inappropriate activation of autoreactive B cells. Viable moth-eaten mice also develop an autoimmune syndrome due to a naturally occurring deficiency in the SHP-1 phosphatase, a potent negative regulator of BCR signaling.⁷⁰ In these mice, B1 cells are responsible for the production of IgM anti-DNA antibodies. Transgenic mice deficient in other signaling molecules that alter threshold activation such as CD22⁶² and Lyn⁶⁴ also produce autoantibodies. Thus changes in thresholds for antigen-induced B cell activation can lead to the activation of autoreactive B cells.

SUMMARY

The generation of a diverse repertoire of antibody molecules provides an important line of defense against microbial infections. The immune system is exquisitely controlled at

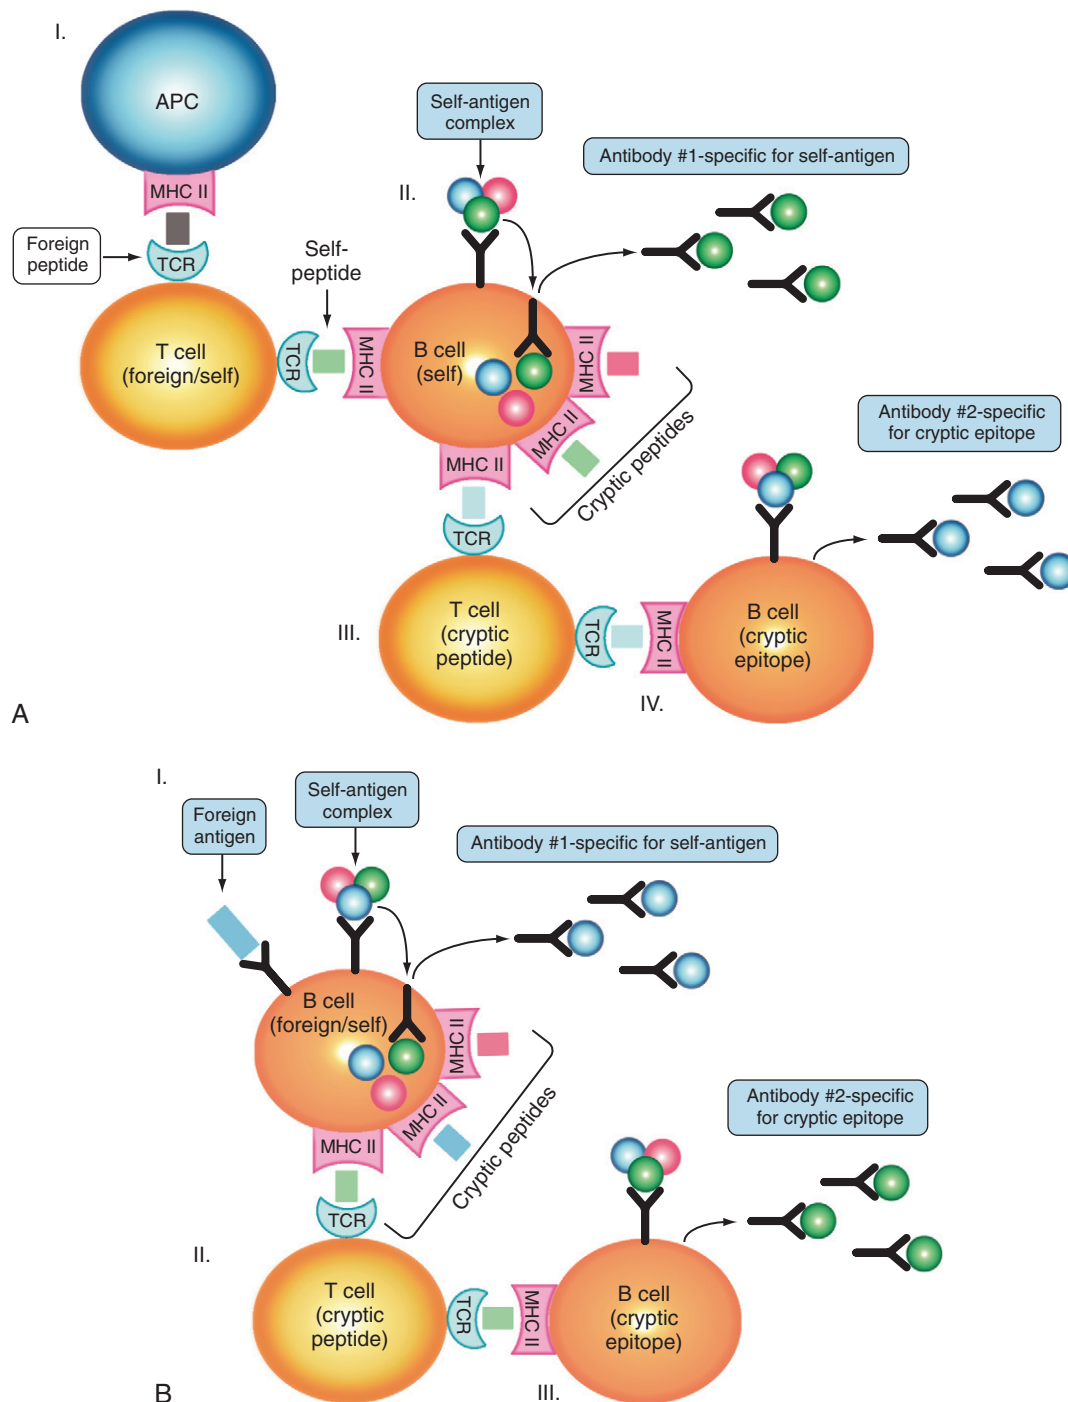

Figure 14-9 Epitope spreading. **A**, Epitope spreading by activation of cross-reactive T cells. *I*, Following antigen presentation of a foreign peptide that is recognized by cross-reactive T cells, co-stimulatory signals are delivered to B cells with surface immunoglobulin receptors that recognize a self-antigen as part of a complex of self-molecules. *II*, The complex is engulfed by a self-reactive B cell, and antibodies specific for self-antigen are generated. *III*, Self-reactive B cells process the self-molecules and present cryptic peptide-MHC II complexes on the cell surface. *IV*, If these cryptic peptides are recognized by nontolerized autoreactive T cells, B cells specific for these cryptic peptides are activated and the autoantibody response spreads to other components of the self-antigen complex. **B**, Epitope spreading by activation of autoreactive B cells. *I*, A foreign antigen that mimics a self-molecule can mediate the endocytosis of a self-molecule that is included in a self-antigen complex. The self-molecules of the complex are processed and expressed on the cell surface of the B cell as cryptic peptide-MHC II complexes. *II*, Cryptic peptides are recognized by nontolerized autoreactive T cells. *III*, These T cells provide co-stimulation to B cells that recognize cryptic peptides, resulting in the production of additional self-reactive antibodies.

Figure 14-10 Selection checkpoints during B cell maturation. Autoreactive B cells can be censored at multiple developmental checkpoints: (1) Following surface expression of surface immunoglobulin, immature B cells that encounter autoantigen in the bone marrow are subject to negative selection. (2) B cells that are not eliminated in the bone marrow may undergo negative selection during the transitional B cell stage. Transitional B cells that emerge from this development stage give rise to follicular (FO) or marginal zone (MZ) B cells. Follicular B cells activated by antigen and the help of cognate T cells progress to the germinal center (GC) B cell stage. (3) Germinal center B cells that acquire high affinity for autoantigen by the process of somatic hypermutation may be eliminated in the germinal center to block their further maturation into long-lived plasma cells or memory cells. (4) There is evidence that autoreactive plasmablasts may also be subject to negative selection. Long-lived plasma cells that emerge from the selection process home primarily to the bone marrow, and memory B cells circulate throughout the periphery. HC, heavy chain; LC, light chain.

multiple levels to allow the maturation of B cells that produce protective antibodies while attempting to avoid the production of autoantibodies (Figure 14-10). Only a small percentage of B cell precursors generated completes the maturation pathway. During the pro-B and pre-B cell stages of development, B cells with aberrantly rearranged H- or L-chain genes are eliminated. As the remaining precursor cells transit into the immature B cell stage, they are subject to negative selection; that is, immature B cells with auto-specificity are either deleted or inactivated, whereas nonautoreactive B cells are released into the periphery. B cells that are stimulated by foreign antigen are selectively expanded and undergo further Ig gene diversification in peripheral lymphoid tissue. During this stage of development, B cells that express high-affinity Ig receptors undergo positive selection, whereas B cells with a diminished affinity or those that have acquired autoreactivity are eliminated. B cells that pass through these critical developmental checkpoints differentiate into long-lived memory B cells or plasma cells. The underlying causes of B cell-associated autoimmunity are not understood, but just as there are multiple checkpoints for the survival or activation of autoreactive B cells, it seems likely that multiple defects in the regulatory mechanisms that control B cell maturation and differentiation contribute to autoimmune disease.

Fibroblasts and Fibroblast-like Synoviocytes

ANDREW FILER • CHRISTOPHER D. BUCKLEY

KEY POINTS

Fibroblasts are programmed epigenetically to determine the unique structure and function of different organs and tissues. However, these unique features might contribute to organ-specific disease.

Tissue fibroblasts may be recruited from a number of sources and cell types including the bone marrow, blood, and local stromal cells and act as organ-specific innate immune sentinel cells.

Under inflammatory conditions, fibroblasts become key immune system players recruiting and modulating the behavior and survival of infiltrating immune cells.

Fibroblasts can be programmed epigenetically through exposure to inflammatory and environmental hits such that they inappropriately prolong inflammation, which becomes persistent.

Within the synovium, this persistent abnormal behavior results in continued damage to vital joint structures such as cartilage and bone, which, if untreated, will result in deformity and functional impairment.

In vivo models allow us to observe and modulate fibroblast behavior; these models have recently revealed the possibility of diseased fibroblasts autonomously moving to different sites in the body.

WHAT IS A FIBROBLAST?

The architecture of organs and tissues is closely adapted to their function in order to provide microenvironments in which specialized functions may be carried out efficiently. The nature and character of such microenvironments are primarily defined by the stromal cells that reside within the tissues. The most abundant cell types of the stroma are fibroblasts, which are responsible for the synthesis and remodeling of extracellular matrix (ECM) components. In addition, their ability to produce and respond to growth factors and cytokines allows reciprocal interactions with adjacent epithelial and endothelial structures and with infiltrating leukocytes. Fibroblasts also act as integrators of microenvironmental stimuli such as oxygen tension and pH. As a consequence, fibroblasts play a critical role during tissue development and homeostasis and are often described as having a “landscaping” function.

Fibroblast Identity and Microenvironments

Tissue-resident macrophages in the liver (Kupffer cells) and lung (alveolar macrophages) perform very different functions compared with macrophages in the brain (glial cells)

or skin (Langerhans cells), yet they are all members of the monocyte/macrophage family. Until recently fibroblasts had been thought of as ubiquitous, generic cells with a common phenotype even within different tissues. However, we now know that fibroblasts from different organs are more like their macrophage counterparts, with unique morphology and repertoires of ECM proteins, cytokines, co-stimulatory molecules, and chemokines specialized to the different microenvironments in which they are found. This also extends to their function as “immune sentinel” cells, expressing innate immune system pattern recognition receptors such as Toll-like receptors (TLRs), which trigger a proinflammatory response when ligated by bacterial or viral determinants. When fibroblast transcriptional profiles are examined using microarray techniques, fibroblasts hold a strong memory of their anatomic position and function in the body. Early studies demonstrated that fibroblast transcriptomes (the global picture of transcribed genes measured using microarrays) could be clustered into peripheral (synovial joint or skin fibroblasts) versus lymphoid (tonsil or lymph node) groups according to their organ of origin, with the potential to shift their transcriptional profiles by treatment with inflammatory mediators such as tumor necrosis factor (TNF), IL-4, or interferon- γ . More extensive analysis of expression profiles from primary human fibroblasts by Rinn and colleagues has shown large-scale differences related to three broad anatomic divisions: anterior-posterior, proximal-distal, and dermal-nondermal. Genes involved in pattern forming, cell-signaling, and matrix remodeling were found to predominantly account for these divisions.¹ The gene expression profile of adult fibroblasts may therefore play a significant role in assigning positional identity within an organism. More recently, it has become clear that these stable changes in gene transcription are brought about through epigenetic activation and silencing of the HOX family of landscaping genes.² Such epigenetic patterning, whereby covalent modifications are made to regulatory regions of DNA, or to the histones around which the DNA is wrapped in order to control access of transcriptional complexes, is a prototype for the stable changes that are also seen in fibroblasts. Epigenetic modifications result in stable changes in gene expression that persist over cellular generations in the absence of mutation of the primary DNA sequence, and which therefore drive the persistence of disease, as is described in more detail in Chapter 22.

Embryologic Origins

The problem of distinguishing fibroblasts of differing origin or maturity has historically been difficult due to a lack of specific cell surface markers. Whereas cluster of

differentiation (CD) markers have revolutionized the isolation and study of leukocyte subsets, there have been relatively few, poor-quality discriminatory markers allowing the identification of fibroblast subpopulations. Fibroblasts have therefore traditionally been identified by their spindle-shaped morphology (Figure 15-1), elaboration of ECM, and lack of positive markers for endothelium, epithelial, and hemopoietic cells.

However, there is growing evidence that fibroblasts are not a homogeneous population but exist as subsets of cells, much like tissue macrophages and dendritic cells. It is likely that connective tissue contains a mixture of distinct fibroblast lineages with mature fibroblasts existing side by side with more immature fibroblasts that are capable of differentiating into other connective tissue cells. Recent studies have begun to identify novel markers that demarcate distinct subpopulations of stromal cells during development and which have the potential to act as markers for different subpopulations of fibroblasts, each with different roles. Such markers include smooth muscle actin, which marks out a population of secretory, activated cells termed *myofibroblasts*, and more recently discovered markers such as CD248 and gp38 (podoplanin) (Table 15-1³⁻¹⁴ and see text later). Fibroblasts have been defined in terms of their embryologic origins and lineage relationships and are

generally considered to be mesenchymal in origin. However, cell populations that appear to blur the distinction between hemopoietic and nonhemopoietic populations have now been identified. In addition, other unexpected shifts in lineage have been reported including differentiation from neural stem cells into myeloid and lymphoid hemopoietic lineage. Classification by such lineages is therefore becoming increasingly untenable.

Origins of Fibroblasts in Tissue

Both inflammation and wound healing are characterized by the formation of new tissue. However, recent findings suggest that the new cells that form the remodeled tissues are not necessarily, as was hitherto assumed, derived from the proliferation of cells that are resident in the adjacent noninjured tissue. This is an important issue because in both RA and fibrotic pathologic conditions, fibroblasts accumulate in excessive numbers despite apparently low proliferative rates. The principle origin for fibroblasts is from primary mesenchymal cells and that on appropriate stimulation fibroblasts can proliferate locally to generate new fibroblasts. In fact, though an increase in fibroblast numbers caused by local proliferation does occur, fibroblasts may arise from other sources (Figure 15-2). The first of these is local epi-

Figure 15-1 Fibroblast phenotype. **A**, Staining and differential interference contrast microscopy of live fibroblast cells in culture illustrating typical morphology and marked differences between synovial fibroblasts of the rheumatoid arthritis joint and skin fibroblasts. Red stain (fibronectin) demonstrates matrix production. Blue stain indicates nuclei. **B**, Stromal cell status is confirmed by fluorescence microscopy of cells showing collagen synthetic enzymes (prolyl-4-hydroxylase) within and matrix production (fibronectin) on the surface of skin fibroblasts.

Table 15-1 Synovial Stromal Markers and Their Geographic and Functional Significance

Marker	Associated Cell Type	Synovial Location	Functional Significance
CD55	Fibroblast-like synovioocyte	Lining layer	Receptor/ligand for synovial macrophage CD97 ³
VCAM-1	Fibroblast-like synovioocyte	Lining layer	Activated lining layer fibroblasts; adhesion molecule ⁴
Alpha-smooth muscle actin (α -SMA)	Myofibroblast	Variable, minority subpopulation	Secretory, profibrotic fibroblast ⁵
CD248/endothelialin	Pericyte	Sublining fibroblasts, pericytes	Acute inflammation, ⁶ cancer and vasculogenesis ⁷
gp38/podoplanin	Pericyte and lymphoid endothelium	Lining layer fibroblasts, pericytes, lymphoid endothelium	Structural, proangiogenic lymph node role ⁸ ; promotes motility in cancer ⁹
5B5/prolyl-4-hydroxylase	Broad fibroblast marker in vivo	Lining and sublining cells	Marks collagen synthetic machinery ¹⁰
S100A4/FSP-1/Mts-1	—	Lining and sublining cells, invasive regions	Cancer, invasiveness roles via motility and impaired apoptosis ¹¹
Fibroblast activation protein (FAP)	Associated with α SMA-positive fibroblasts ¹²	Lining layer	Role in cancer fibroblasts, ¹³ protective if ectoenzyme blocked in rheumatoid arthritis ¹⁴

thelial to mesenchymal transition (EMT). This is an essential, physiologically important developmental mechanism for diversifying cells in the formation of complex tissues. However, fibroblasts also appear to be derived by this process in adult tissue following epithelial stress such as inflammation or tissue injury. EMT both disaggregates epithelial cells and reshapes them for movement. The epithelium loses polarity as defined by the loss of adherens junctions, tight junctions, desmosomes, and cytokeratin intermediate filaments. Epithelial cells also rearrange

their F-actin stress fibers and express filopodia and lamellipodia. A combination of cytokines and matrix metalloproteinases (MMPs) associated with digestion of the basement membrane is believed to be secreted and important in the process. The transition of epithelial to mesenchymal cell populations has been shown to occur in cancer and in diseases of the lung and kidney in which the process has been implicated in fibrotic disease.¹⁵ Early evidence suggests that a similar process may occur within the RA synovium.¹⁶

Figure 15-2 Routes of differentiation to tissue fibroblasts. In response to wounding or inflammation, increased numbers of fibroblasts are produced within tissue. 1, Fibroblasts can proliferate locally to generate new fibroblasts. 2, The transition of epithelial to stromal cell populations has been shown to occur in cancer and diseases of the lung, kidney, and possibly the synovium. 3, Fibrocytes arise from the monocyte population in blood and then differentiate toward fibroblasts in tissue. 4, Blood-borne mesenchymal progenitor cells (MPC) may be recruited to tissues and undergo local differentiation to tissue fibroblasts. EMT, epithelial to mesenchymal transition.

An alternative explanation for the accumulation of stromal cells in chronic inflammatory conditions such as rheumatoid arthritis (RA) lies in the possibility of blood-borne precursors. In the mid 1990s it was shown that vascular precursors (angioblasts) could be found circulating in the blood of normal individuals and that they could be recruited to sites of vasculogenesis in a rabbit ischemic hind limb model.¹⁷ This demonstrated that circulating mesenchymal precursors exist outside the hemopoietic system. Subsequent work has confirmed the presence of circulating cells of a mesenchymal phenotype in human subjects. These cells bear a remarkable resemblance to the synovial fibroblasts found in the joints of patients with RA, which accumulate in large quantities in the joint lining despite little evidence of proliferation. Interestingly, Marinova-Mutafchieva and colleagues¹⁸ showed that an influx of such cells preceded inflammation in a mouse collagen-induced arthritis model, suggesting that there may be a role for blood-borne stromal cell precursors in the initiation of inflammatory diseases. Furthermore, evidence now exists to show that synovial fibroblasts themselves may migrate in the bloodstream, at least between distant sections of human cartilage in SCID mice,¹⁹ raising an intriguing parallel to cancer and the radical concept of RA as a metastatic disease of the stroma.

Another circulating precursor cell that could account for the accumulation of fibroblasts in disease is the fibrocyte. Fibrocytes appear to comprise 0.1% to 0.5% of nonerythrocytic cells in peripheral blood and have been shown to rapidly enter sites of tissue injury and contribute to tissue remodeling in models of inflammatory lung disease.²⁰ They are adherent cells with a spindle-shaped morphology that express MHC class II and type I collagen and which arise from within the CD14⁺ (monocyte) fraction of peripheral blood.²¹ Fibrocytes are capable of matrix elaboration and differentiate along fibroblast lineages under the influence of cytokines, particularly transforming growth factor- β (TGF- β). The mere fact that a cell type apparently arising from within the monocyte lineage may become a “mesenchymal” stromal cell such as a fibroblast implies a further degree of plasticity and blurring of the apparently clear dividing line previously thought to exist between hemopoietic and non-hemopoietic lineages.

Fibroblasts versus Mesenchymal Progenitor Cells

The potential role of circulating mesenchymal cell precursors (variously termed *mesenchymal stem cells* [MSCs], *mesenchymal stromal cells*, or *mesenchymal progenitor cells* [MPCs]) as sources of tissue fibroblasts is highlighted by the remarkable capacity of these cells to differentiate into other members of the connective tissue family including cartilage, bone, adipocyte, and smooth muscle cells. This ability was initially demonstrated in bone marrow stromal cells, RA synovial fibroblasts, and circulating mesenchymal cells. Therefore it was suggested to define a characteristic mesenchymal phenotype on the basis of the hypothesis that the rheumatoid synovium could become populated by a large proportion of circulating mesenchymal progenitor cells exported from the bone marrow. However, the property of trilineage differentiation (“pluripotentiality”) has now been

shown to be a property of many adult tissue fibroblasts, though varying somewhat between fibroblasts from different tissues, implying a hitherto unsuspected degree of plasticity in the body's stromal cell populations.²² The two previously separate fields of mesenchymal precursor cell biology and largely disease-centered fibroblast biology have therefore rapidly converged. However, the concept of bone marrow stromal precursors remains interesting; in chimeric murine models with bone marrow GFP expression, arthritic joints contained significantly more GFP-positive+ cells than non-arthritic joints, supporting a bone marrow origin for expanded fibroblast populations.²³

PHYSIOLOGIC CHARACTERISTICS AND FUNCTIONS OF FIBROBLASTS

Production of ECM Components

Ensuring the homeostasis of the ECM is one of the primary functions of fibroblasts. In order to do this, fibroblasts must be capable of both producing and degrading ECM, as well as adhering to and interacting with existing matrix components. Fibroblasts produce a number of ECM molecules, both fibrous proteins and polysaccharide gel components such as collagens, fibronectins, vitronectin, and proteoglycans, which are then assembled into a three-dimensional network. This provides a framework through which other cell types, which use varying strategies to navigate through the ECM, can move²⁴ and also provides a substrate for the deposition of haptotactic (tissue rather than fluid-based) gradients of chemokines and stores of growth factors to direct cellular movement and behavior in a regional fashion.²⁵ The types of ECM molecules produced by individual populations of fibroblasts differ from tissue to tissue, reflecting the diversity of fibroblasts in different organs. For example, dermal fibroblasts produce significant amounts of type VII collagen, which adheres the epidermal and dermal layers in the skin. Fibroblasts in other organs such as the lung and kidney produce mainly interstitial, fibrillar collagens (particularly types I and III).

In the synovial membrane, fibroblasts also have a barrier function, in that they provide the joint cavity and the adjacent cartilage with lubricating molecules such as hyaluronic acid and with plasma-derived nutrients. Anatomically, the intimal synovial membrane is an unusual structure in that barrier function is maintained in the absence of a laminin-rich basement membrane, as is seen in epithelial structures. In addition to lacking a basement membrane, cellular contacts between the fibroblast-like synoviocytes also lack tight junctions and desmosomes. However, a strong homophilic adhesion between synoviocytes is mediated by the adhesion molecule cadherin-11 (see later), which is largely responsible for fibroblast organization into synovial tissue. In disease, fibroblasts have to migrate to sites of tissue injury or remodeling and interact with ECM molecules through specific surface receptors. Through such receptors, fibroblasts must sense changes in both the structure and the cellular composition of connective tissues. They respond dynamically by adjusting the production of ECM components and cross-linking them into the appropriate matrix.

Attachment to and Interaction with Extracellular Matrix

Integrins

Integrins are key mediators of both cell-to-matrix and cell-to-cell adhesive interactions. They are expressed as transmembrane heterodimers containing one α - and one β -subunit, of which at least 25 $\alpha\beta$ combinations are known (Table 15-2). $\alpha_1\beta_1$ and $\alpha_2\beta_1$ Integrins are the main adhesion molecules responsible for the attachment of fibroblasts to collagen, while other β_1 integrins such as $\alpha_4\beta_1$ and $\alpha_5\beta_1$ integrins mediate attachment of fibroblasts to fibronectin and its spliced variants. In addition, α_v integrins are responsible for attachment to vitronectin.

Syndecans

In addition to conventional integrin-to-ligand binding, additional accessory molecules allow for the integration of adhesive contacts and local growth factor signaling. Syndecans are a family of four single transmembrane domain proteins that carry three to five heparan sulfate and chondroitin sulfate chains, allowing for interaction with a large variety of ligands including fibroblast growth factors, VEGF, TGF- β , and ECM molecules such as fibronectin.²⁶ Syndecans are expressed on fibroblasts in a tissue-specific and development-dependent manner. Data from syndecan knockout mice indicate that syndecan-4 is involved in wound healing, and the response of syndecan-4- deficient fibroblasts to fibronectin attachment is significantly altered.²⁷

Immunoglobulin Superfamily Receptors

The immunoglobulin superfamily is a diverse group of transmembrane glycoproteins defined by the presence of one or more immunoglobulin-like repeats of 60 to 100 amino acids

with a single disulfide bond.²⁸ While including numerous adaptive immune system genes (immunoglobulins, T cell receptor, major histocompatibility complex), adhesion proteins such as ICAMs 1 to 3, VCAM-1, and MadCAM mediate both cell-to-cell interactions and adhesive interactions with integrins (see Table 15-2).

Cadherins

Cadherins mediate homotypic, calcium-dependent adhesive interactions with the same cadherin species expressed by neighboring cells.²⁹ Classical cadherins possess five extracellular domains, a single-pass transmembrane domain, and a highly conserved cytoplasmic tail. The cytoplasmic tail interacts with β -catenin, which in turn binds α -catenin, forming a linkage between the cadherin-catenin complex and the actin cytoskeleton. Tightly regulated expression of cadherins is essential to embryogenesis but is also critical for tissue morphogenesis and tissue-specific cell differentiation. Cadherins also modulate cell proliferation and invasion through activation of intracellular signal transduction pathways, modulation of matrix metalloproteinase production, and association with growth factor receptors.³⁰⁻³²

Importantly, interaction with adhesion molecules not only regulates adhesion and motility but also directly influences activation status, apoptosis, and proinflammatory and anti-inflammatory responses in fibroblasts and other cells. The engagement of cell adhesion molecules such as integrin receptors on the surface of fibroblasts results in the formation of focal adhesion complexes, which activate intracellular signaling cascades regulating cell proliferation and survival, the secretion of certain cytokines and chemokines, and matrix deposition and resorption. In particular, integrin-to-fibronectin engagement induces matrix metalloproteinase expression, linking adhesion-to-matrix remodeling³³

Table 15-2 Cell Adhesion Molecules (CAMs) and Their Receptor/Ligand Molecules

Family	CAM	Alternative Names	Ligands
Integrins	$\alpha_1\beta_1$	VLA-1	Laminin, collagen
	$\alpha_2\beta_1$	VLA-2	Laminin, collagen
	$\alpha_3\beta_1$	VLA-3	Laminin, collagen, fibronectin
	$\alpha_4\beta_1$	VLA-4, CD49d/CD29	VCAM-1, CS1 fibronectin
	$\alpha_5\beta_1$	VLA-5	Fibronectin
	$\alpha_6\beta_1$	VLA-6	Laminin
	$\alpha_L\beta_2$	LFA-1, CD11a/CD18	ICAM-1, ICAM-2, ICAM-3, JAM-A
	$\alpha_M\beta_2$	Mac-1, CR3, CD11b/CD18	ICAM-2, iC3b, fibrinogen, factor X
	$\alpha_X\beta_2$	P150, 95, CD11c/CD18	iC3b, fibrinogen
	$\alpha_E\beta_2$		E-cadherin
	$\alpha_4\beta_7$	CD49d	Fibronectin, VCAM-1, MadCAM-1
	$\alpha_v\beta_3$	CD52/CD61, vitronectin receptor	Vitronectin, fibronectin, osteopontin, thrombospondin-1, tenascin
Ig Superfamily	ICAM-1	CD54	LFA-1, Mac-1
	ICAM-2		LFA-1
	ICAM-3		LFA-1
	VCAM-1		$\alpha_4\beta_1$, $\alpha_4\beta_7$
	MadCAM-1		$\alpha_4\beta_7$, L-selectin
Cadherins	E-cadherin	Cadherin-1	E-cadherin
	N-cadherin	Cadherin-2	N-cadherin
	Cadherin-11	OB-cadherin	Cadherin-11

ICAM, intercellular adhesion molecule; JAM, junctional adhesion molecule; LFA, lymphocyte function-associated antigen; MAdCAM, mucosal addressin cell adhesion molecule; VCAM, vascular cell adhesion molecule; VLA, very late antigen.

CRITICAL SIGNALING PATHWAYS IN SYNOVIAL FIBROBLASTS

Figure 15-3 Important signaling pathways in synovial fibroblasts. **A**, Integrin signaling in fibroblasts. The engagement of integrins and extracellular matrix-bound growth factors on the cell surface of fibroblasts results in the initiation of signaling cascades that result in changes in (1) cell motility through reorganization of the cytoskeleton, (2) cell survival (e.g., through activation of the Akt-NFκB pathway), and (3) the production of matrix molecules, matrix-degrading enzymes, and soluble mediators through the activation of mitogen-activated protein kinases (MAPK). **B**, The three (MAPK) pathways are also pivotal in proinflammatory cytokine activation of synovial fibroblasts, with TNF, IL-1β, and IL-6 all capable of activating the three main pathways. In particular, JNK and p38 MAPK pathways are crucial to the production of MMPs such as the collagenases. Fos family members and jun dimerize to form the activator protein-1 (AP-1) transcription factor for which binding sites are present on multiple proinflammatory genes including the MMPs. **C**, There is evidence for a discrete proinflammatory pathway for some ligands, which may bypass the classical MAPK and NFκB/AP-1 pathways, signaling via PI3K to elicit secretion of chemokines. The chemokines specifically recruit the mononuclear cell population, which predominates in persistent inflammatory disease.

(Figure 15-3). Among the signaling molecules that transmit signals from the integrins to the cell interior, focal adhesion kinase (FAK) plays a central role.³⁴ FAK, a tyrosine kinase, is recruited into newly established focal contacts and, in turn, recruits other adapter proteins such as p130Cas and Grb2. This leads to the activation of phosphatidylinositol 3-kinase (PI3K) and Src-kinase and promotes the initiation of a variety of signaling cascades, culminating in the ERK MAPKs and activation of transcription factors. Such pathways can also be activated through FAK-independent signaling events, such as through growth factor receptor ligation. The exact mechanisms by which different signals cooperate to mediate a specific response of fibroblasts and

how this translates into distinct pathologies are not yet fully defined.

Degradation of Extracellular Matrix by Fibroblasts

Remodeling of the ECM requires fibroblasts to express an extensive repertoire of matrix-degrading enzymes with varying specificity. Although these are crucial to tissue maintenance and repair, inappropriate overexpression of such enzymes is a key factor in the joint damage, particularly to cartilage, which occurs in inflammatory disease. Such enzymes fall into a number of families including matrix

metalloproteinases (MMPs), tissue inhibitors of metalloproteinases (TIMPs), cathepsins, and aggrecanases. These are covered in detail in Chapter 8.

With the exception of MMP-2 and the MT-MMPs, which are constitutively expressed by fibroblasts, MMP expression is regulated by extracellular signals via transcriptional activation in fibroblasts. Three major groups of inducers can be differentiated: proinflammatory cytokines, growth factors, and matrix molecules. Among the cytokines, IL-1 is perhaps the most potent inducer of a variety of MMPs including MMP-1, MMP-3, MMP-8, MMP-13, and MMP-14. Fibroblast growth factor (FGF) and platelet-derived growth factor (PDGF) are also known inducers of MMPs in fibroblasts because they potentiate the effect of IL-1 on MMP expression. All MMP promoter regions except MMP-2 contain activator protein-1 (AP-1) binding sites; however, there is good evidence that all MAPKinase families (ERK, JNK, and p38 pathways) (see [Figure 15-3](#)), in addition to activators of NF κ B, STAT, and ETS transcription factors participate in MMP regulation.³⁵⁻³⁹ Matrix proteins (collagen, fibronectin) and especially their degradation products also activate MMP expression in fibroblasts, providing the possibility for site-specific MMP activation in regions of matrix breakdown.⁴⁰

Fibroblasts as Innate Immune Sentinels

Classically, macrophages have been studied as sources of inflammatory cytokines and chemokines in response to innate immune stimuli and portrayed as immune sentinel cells accordingly. However, when activated by substances released during tissue injury or the products of invading microorganisms, fibroblasts are capable of elaborating a broad repertoire of inflammatory mediators, which fully justifies their classification as immune sentinel cells. Through expression of TLRs 2, 3, and 4, fibroblasts respond to bacterial products such as LPS by activating the classical NF κ B and AP-1 inflammatory pathways, generating chemokines capable of recruiting inflammatory cells, and generating metalloproteinases capable of degrading matrix.⁴¹⁻⁴³ However, TLR expression may be increased by proinflammatory cytokines TNF and IL-1 β within the local microenvironment⁴⁴ and may also be activated by endogenous cellular debris such as necrotic cells in synovial fluid, leading to widespread fibroblast activation in disease.⁴⁵ As immune sentinels, fibroblasts are capable of bridging the innate and adaptive immune responses through expression of the molecule CD40. This molecule was initially assumed to be restricted in its expression to antigen-presenting cells such as macrophages and dendritic cells. However, it is widely expressed by fibroblasts within discrete tissues. Engagement of CD40 by its ligand CD40L expressed on a restricted population of immune cells including activated T lymphocytes is critical for the further induction of proinflammatory cytokines and chemokines during an immune response, as well as for antibody production by CD40-expressing B lymphocytes. Fibroblasts also need to be able to respond to more generic danger signals. The intracellular apparatus for response to danger signals such as high levels of urate has recently been identified as the NOD-like receptor family made up of NOD (nucleotide-binding oligomerization domain) and NALP (NACHT domain, leucine-rich-repeat

[LRR] domain, and pyrin domain [PYD]-containing protein) receptors. A high local level of urate released by dying cells triggers formation of the active NALP3 inflammasome complex, which results in release of IL-1.⁴⁶ Expression of high levels of NOD-2 and NALP3 (cryopyrin) are seen in the RA synovium and can be induced in fibroblasts by TLR ligands and/or TNF,^{47,48} although their relationship with as yet unidentified ligand molecules remains unclear; the NOD-2 ligand muramyl dipeptide is, however, present in the bowel, where it has a role in driving inflammation in Crohn's disease.

Role of Specialized Fibroblast Subsets within Tissue Microenvironments

Combining surface markers with consistent function has been the key to decades of development in the field of leukocyte biology. By comparison, stromal cell biologists have had remarkably few such stable markers. However, this situation is now gradually changing and certain areas of developmental biology have spearheaded identification of putative markers (such as CD248) through approaches such as immunization of animals with human fibroblasts and digesting and identifying stromal cell subpopulations in tractable organ systems. One such example is the murine thymic stroma, in which subsets with both geographic and functional consistency have been identified. For instance, Link and colleagues⁴⁹ identified CD45⁻, gp38-positive cells, which were not lymphatic endothelium (CD31⁻) in the thymus as T-zone fibroblastic reticular cells. This population of cells geographically restricted to the T zone provides a limited pool of essential homeostatic survival factors, IL-7 and CCL19, for T lymphocytes, serving a key niche function for which adaptive immune cells must compete.⁴⁹

A further subpopulation of specialized fibroblast-like cells of mesenchymal origin is the pericyte. These cells ensheath small blood vessels (arterioles, capillaries, and venules) and are involved in vasculogenesis, matrix stabilization, and immunologic defense. Pericytes have been hypothesized to represent the extralymphoid source of mesenchymal progenitor cells and express markers consistent with mesenchymal stem cells. Their further definition with newer stromal cell markers will be able to establish a mesenchymal progenitor cell niche.⁵⁰

Fibroblast-like Synoviocytes in the Normal Synovium

The normal synovium provides an excellent prototypic model of fibroblast subsets defined by known markers, some of which are responsive to disease. In health the synovium is a delicate, thin structure attaching bone and the joint capsule. It is divided into two layers. One is a two- to three-cell thick lining layer, which is formed in roughly equal proportions of CD68⁺, phagocytic type A macrophage like synoviocytes and type B mesenchymal, fibroblast-like synoviocytes (FLS). This layer must subserve a barrier function, and FLS must secrete lubricative substances including hyaluronic acid and lubricin, as well as secreting the lining layer matrix. The second layer is the sublining layer, which is composed of less densely packed fibroblasts and

macrophages in a loose tissue matrix along with blood vessel networks. FLS in the lining layer are associated with a number of cellular markers (see [Table 15-1](#)) including CD55 (decay accelerating factor [DAF]), VCAM-1 (which outside T cell-to-integrin interactions is generally only expressed by bone marrow fibroblasts providing support for the B cell developmental niche⁵¹), uridine diphosphoglucose dehydrogenase (UDPGD) reflecting the ability to synthesize hyaluronan, and the novel marker gp38.⁵² Sublining FLS are instead marked by the nonspecific cellular marker CD90 (Thy-1), which also recognizes endothelium, and by the recently discovered marker CD248, which marks both pericytes and stromal fibroblasts. Gp38 marks cells in the sublining region including lymphatic endothelium and pericytes ([Figure 15-4](#)). As mentioned earlier, the unique lining layer barrier function is supported not by a basement membrane and conventional tight junctions but by homotypic interactions between cadherin-11 molecules.⁵³ Randomly assorted cells expressing classical cadherins such as cadherin-11 will sort themselves in a cadherin-specific manner, emphasizing their importance in the generation and maintenance of organ integrity. Cadherin-11 mediates selective association of mesenchymal rather than epithelial tissues, a function that is carried forward after embryogenesis in structures such as the joint lung and testis.⁵⁴ Cadherin-11 knockout mice exhibit a hypoplastic synovial lining that lacks the normal numbers of synovial lining cells and is deficient in ECM

quantity.⁵⁵ Adhesion between type A and type B synovio-cytes is maintained by ICAM-1: β_2 integrin and VCAM-1: $\alpha_4\beta_1$ integrin interactions.

By virtue of their role in defining the geography of specialized tissues, fibroblasts and other stromal cells exist in living organisms within three-dimensional environments, whereas the vast majority of experiments performed using fibroblasts in the laboratory are still conducted within two-dimensional environments. Furthermore, fibroblasts are frequently grown in nonphysiologic stimuli such as serum, to which fibroblasts would not normally be exposed unless tissue damage were to occur. It has been shown that behavior is significantly different when cells are cultured in artificial three-dimensional environments.⁵⁶ It is therefore all the more remarkable that fibroblasts cultured using conventional two-dimensional techniques retain characteristics such as positional memory and unique cytokine profiles. Recent work has addressed the issue of three-dimensional synovial models. In so-called “micromass cultures,” FLS but not dermal fibroblasts within matrigel spheres reproduced a lining layer structure with production of lubricin, co-culture within a lining layer-type structure of cells of monocyte origin, and expansion of the membrane on stimulation with proinflammatory stimuli such as TNF; some cells remained in a “sublining” zone of low density as well.⁵⁷ FLS therefore have the ability to self-organize in a tissue organoid, which recapitulates some of the key features

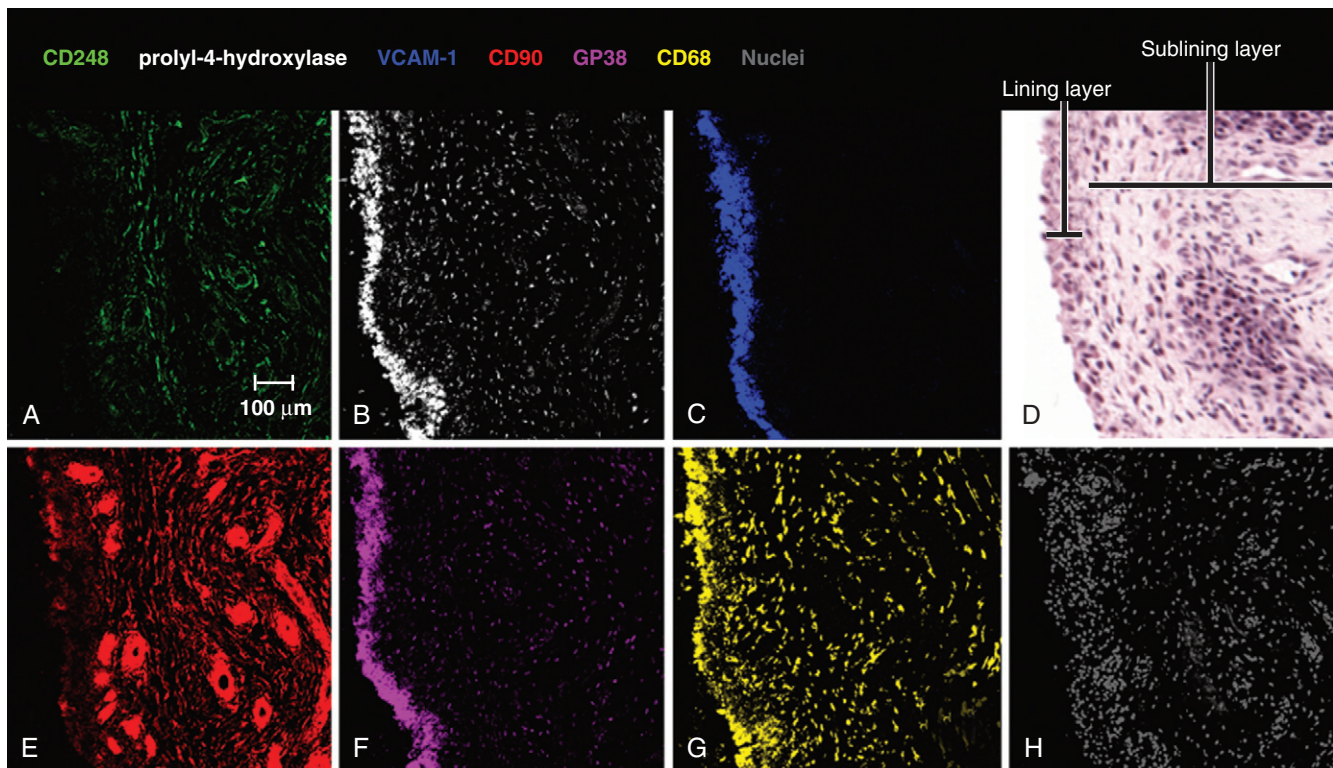

Figure 15-4 Microscopic appearance of the synovium and stromal cell markers. The microscopic structure of hematoxylin and eosin-stained synovium is illustrated in **D**, indicating lining and sublining layers. This geographic structure is reflected in serial frozen sections of rheumatoid arthritis synovium stained for stromal markers (**A-C, E-G**). For reference, a nuclear stain is shown in **H**. **A**, CD248 stains only sublining fibroblasts. **B**, Prolyl-4-hydroxylase stains most populations of synovial fibroblasts. **C**, VCAM-1 (CD106) characteristically stains only the lining layer. **E**, CD90 (Thy-1) stains predominantly sublining layers but also strongly stains endothelial cells, outlining synovial vasculature. **F**, GP38 marks lining layer cells and a proportion of sublining cells. **G**, CD68 highlights macrophage-like synovial cells in the lining layer and resident tissue macrophages in the sublining layer.

of the synovium. This is further evidence of the robustness of epigenetic programming, which determines site and organ specialization.

FIBROBLASTS IN RHEUMATIC DISEASES

Role of Fibroblasts in Persistent Inflammation

Inflammatory reactions proceed against the backdrop of specialized stromal microenvironments. The response to tissue damage involves a carefully choreographed series of interactions among diverse cellular, humoral, and connective tissue elements. In order for an inflammatory lesion to resolve, dead or redundant cells that were recruited and expanded during the active phases of the response must be removed. In addition, resident fibroblasts attempt to repair damaged tissue. It is becoming increasingly clear that fibroblasts are not only passive players in immune responses but also active players in determining the switches that govern progression from acute to chronic inflammation, as well as those governing resolution or the progression to chronic, persistent inflammation. The “switch to resolution” is an important signal that permits tissue repair to take place and enables immune cells to return to draining lymphoid tissues (lymph nodes) in order for immunologic memory to become established. However, in chronic immune-mediated inflammatory diseases such as RA, fibroblasts contribute to the inappropriate recruitment and retention of leukocytes in a site- or organ-dependent manner, leading to tissue- and site-specific initiation and subsequent relapse of chronic persistent inflammatory disease, effectively a “switch to persistence.”⁵⁸

It is now recognized that fibroblasts themselves may undergo fundamental changes while responding to such environmental stimuli. It is known that during wound healing and under profibrotic conditions, some fibroblast-like cells are transformed into myofibroblasts, which are distinct from tissue fibroblasts in terms of both their phenotype and their behavior.⁵⁹ The mechanisms underlying such persistent phenotypic change, which is maintained through cellular generations, are highly likely to involve epigenetic modifications of gene promoters and their closely related histones (see Chapter 22). This has been recently shown in both human and murine renal fibrotic disease, where hypermethylation of the promoter region of a ras oncogene inhibitor led to gene silencing, ras pathway activation, and hence persistent fibrogenesis.⁶⁰ Such fibrotic transformation of fibroblasts is also characteristic of systemic sclerosis, a generalized fibrotic disorder that affects the skin and various internal organs such as the lungs, heart, and gastrointestinal tract (see Chapter 83). The overproduction of ECM components, particularly type I, III, VI, and VII collagen, by skin fibroblasts is a hallmark of this disease and is closely linked to the disease-specific activation of these fibroblasts. This pattern of activation includes not only a distinct profile of ECM overproduction but also altered responses to both inflammatory mediators and immune cells.⁶¹ Although the phenotype of fibroblasts in RA is not fundamentally profibrotic in this sense, the hallmark of these cells, both in vitro and in vivo, is also a persistently imprinted phenotype that is maintained even in the absence of continuous stimulation by inflammatory triggers or leukocytes.

FIBROBLAST-LIKE SYNOVIOCYTES IN RHEUMATOID ARTHRITIS

In inflammatory arthritis such as RA, the two compartments of the synovium undergo radical change. The lining layer undergoes dramatic hyperplasia, sometimes reaching 10 to 15 cells in depth with both type A and type B cell populations expanded and becoming merged with the sublining. At the articular borders of the synovium, the thickened synovial lining layer may become a mass of “pannus” tissue rich in FLS and osteoclasts, which aggressively invade the adjacent articular cartilage and subchondral bone. The sublining layer undergoes expansion as well, with sometimes huge infiltrates of inflammatory cells including macrophages, mast cells, T cells, B cells, and plasma cells in addition to dendritic cells. T and B lineage cells may remain in diffuse infiltrates or may coalesce into aggregates of cells varying from simple perivascular “cuffs” a few cells in diameter to structures resembling B cell follicles in up to 20% of samples.⁶² This increased activity is supported by further ECM production and neoangiogenesis, although the inflamed synovium remains in a state of relative hypoxia.⁶³

As mentioned earlier, cadherin-11 serves a vital role in preserving the integrity of the synovial lining layer, and cadherin-11 knockout mice display a hypoplastic lining layer. However, both knockout mice when exposed to the K/BxN serum transfer model and cultured fibroblasts with mutant cadherin-11 constructs demonstrate impaired invasiveness into cartilage, with a 50% reduction in overall inflammation in the mouse model.^{55,64} Cadherin-11 expression is also much stronger in RA than osteoarthritis (OA) or normal synovium. This unique structural molecule may therefore emerge as a therapeutic target.⁵⁵

Persistent Activated Fibroblast Phenotype in the Rheumatoid Arthritis Synovium

Increased expression of cadherin-11 is but one facet of the persistent, activated phenotype of rheumatoid FLS, which remains stable even after culturing in vitro for many months. These cells play a direct role in tissue damage through secretion of multiple matrix metalloproteinases and cathepsins, which degrade cartilage and bone tissues in the joint. In vitro functional assays such as the matrigel invasion assay produce intriguing results, in which the degree of invasion with a given in vitro cultured fibroblast sample correlates with the degree of radiographic progression seen in the joints of the patient from whose samples the fibroblasts were initially cultured.⁶⁵ The most compelling evidence for a persistent phenotype is the attachment to and invasion of fibronectin-rich matrix such as human cartilage in the absence of functioning leukocyte immune cells in the SCID mouse model of arthritis.⁶⁶ Here, fibroblasts in a tissue construct with human cartilage are implanted under the kidney capsule or skin of immune-incompetent SCID or Rag^{-/-} mice. Multiple-passage cultured rheumatoid, but not osteoarthritis or normal FLS, invade and destroy the co-implanted human cartilage. This model has been used to explore the in vivo mechanisms governing invasiveness. Targeting MMP-1 and cathepsin L using ribozymes inhibits cartilage destruction.^{67,68} The effectiveness of glucocorticoids and the relative efficacy of different formulations of methotrexate in

preventing erosions have also been examined.^{69,70} Of most recent interest, fibroblasts implanted with cartilage will migrate to a contralateral cell-free implant and that subcutaneous, intraperitoneal, and intravenously injected fibroblasts will also migrate to sections of human cartilage, suggesting a tropism to damaged cartilage tissue.¹⁹

This raises the question of which cell populations are grown from the synovium when tissue is digested and adherent cells are cultured *in vitro*: lining layer cells, sublining cells, or a mixture of both? This is a challenging question to answer from a methodologic perspective. However, we do know from transcriptomic approaches that what is cultured remains more stable than might be expected, with little transcriptional divergence over the first two to four passages and the level of differentially expressed genes between parallel cultures rising to over 10% only after passage 7.⁷¹

These models demonstrate the remarkably stable and disease-specific phenotype of cultured RA synovial fibroblasts, which includes high basal and stimulated expression of signature cytokines such as IL-6 and chemokines (discussed later).⁷² RA synovial fibroblasts also express characteristic adhesion and immune-modulating molecules such as VCAM-1, galectin-3, and a specific repertoire of TLRs, which initiate innate immune cellular responses. A satisfactory molecular explanation for the stable phenotype of RA synovial fibroblasts has until recently evaded the field. However, epigenetic changes including DNA methylation, histone modifications such as acetylation, and microRNA expression have now been suggested to underlie the observed persistent changes in fibroblast gene transcription and post-transcriptional repression (see Chapter 22). Further characteristic aspects of the RA FLS phenotype and their biology are discussed extensively in Chapter 69.

Interactions of Fibroblasts with Leukocytes

Recruitment of Inflammatory Infiltrates into the Joint

Stromal elements such as synovial fibroblasts are subject to a proinflammatory cytokine network within the inflamed synovium. Direct-contact interactions with other infiltrating cells such as T lymphocytes lead to high levels of expression of many inflammatory chemokines (see Figure 15-3). Neutrophil-attracting chemokines are expressed at high levels by stimulated fibroblasts and include CXCL8 (IL-8); CXCL5 (epithelial-cell-derived neutrophil attractant 78, ENA-78); and CXCL1 (growth-related oncogene alpha, GRO α).⁷³⁻⁷⁵ Monocytes and T cells are recruited by a range of chemokines found at high levels in the synovium; CXCL10 (IP-10) and CXCL9 (Mig) are highly expressed in synovial tissue and fluid.⁷⁶ CXCL16 is also highly expressed in the RA synovium and acts as a potent chemoattractant for T cells.⁷⁷ CCL2 (MCP-1) is found in synovial fluid and known to be produced by synovial fibroblasts; it is considered to be a pivotal chemokine for the recruitment of monocytes.⁷⁸ CCL3 (Mip-1 α), CCL4 (Mip-1 β), and CCL5 (RANTES) are chemotactic for monocytes and lymphocytes and are known products of synovial fibroblasts.^{76,79} CCL20 (MIP-3 α) is also overexpressed in the synovium and has a similar chemoattractant profile via its specific receptor, CCR6.⁸⁰ CX3CL1 (Fractalkine) is also widely expressed

in the rheumatoid synovium. A number of chemokine receptors have been shown to differ between peripheral blood and synovial leukocytes, suggesting that they are enriched in the synovium either through their selective recruitment by endothelial-expressed chemokines or following upregulation by the microenvironment after their recruitment.

Fibroblast Support for Leukocyte Survival

Stromal cell support for the survival of leukocyte populations fulfills a physiologic role in certain organs within the body. The selective recruitment and support of hemopoietic subsets is an essential physiologic function of stromal cells in specific microenvironments. For instance, immature B lymphocytes are completely dependent on factors such as IL-6 produced by bone marrow stromal cells. Although the bone marrow niche plays a critical role in the early development of all hemopoietic leukocyte populations, it also acts as an active reservoir for terminally differentiated leukocyte subpopulations including CD4 and CD8 T cells and neutrophils. The bone marrow stromal microenvironment therefore maintains not only the selective survival, differentiation, and proliferation of all lineages of immature hemopoietic cells but also in some cases the survival of their mature counterparts. The stromal microenvironment plays a crucial role in the maintenance of such survival niches, which are not generic, but highly specific to certain organs and tissues, resulting in site-specific differences in the ability of different stromal cells to support the differential accumulation of leukocyte subsets.

In the case of an inflammatory response, successful resolution requires the removal of the vast majority of immune cells that were recruited and expanded during the active phase of the inflammation. A number of studies have shown that during the resolution phase of viral infections, the initial increase in T cell numbers in peripheral blood that is seen within the first few days is followed by a wave of apoptosis occurring in the activated T cells. This situation is mirrored within tissues, where apoptosis induced by the molecule Fas occurs at the peak of the inflammatory response and may be responsible for limiting the extent of the immune response. In contrast, the resolution phase appears to be principally triggered by cytokine-deprivation-induced apoptosis, during which leukocytes compete for a shrinking pool of survival factors provided by the microenvironment, leading to programmed death of those cells, which are surplus to requirements.

In RA the resolution phase of inflammation becomes disordered. Recent studies have shown that a failure of synovial T cells to undergo apoptosis contributes to the persistence of the inflammatory infiltrate. The T cell survival pathway shares all the essential hallmarks of a stromal cell, cytokine-mediated mechanism (high Bcl-X_L, low Bcl-2, and lack of cell proliferation). Type I interferons (interferons α and β), produced by synovial fibroblasts and macrophages, have been identified as one of the principal factors responsible for prolonged T cell survival in the rheumatoid joint (Figure 15-5).⁵⁸ Interestingly, although type I interferon has been shown to be beneficial in multiple sclerosis (a disease in which tissue scarring and low levels of T cell infiltrates are observed), these results suggest that type I

Figure 15-5 Cell-cell interactions in the synovium. Synovial fibroblasts interact with multiple cell types in the rheumatoid arthritis (RA) synovium to maintain persistence of inflammation and continued joint destruction. **A**, Fibroblast-like synoviocytes in the RA synovial lining interact with macrophage-like synoviocytes through both secretion of soluble factors and cell surface receptor interactions to maintain lining layer structure and promote the activation of both cell types. Key soluble interactions include production of IL-1 and TNF by macrophages and IL-6 by fibroblasts. Adhesive interactions consist of integrin-receptor interactions as described in the text and the critical presence of homotypic interaction through cadherin-11. **B**, Sublining synovial fibroblasts interact with numerous cell types including mast cells and plasma cells (not shown), T cells, B cells, interstitial macrophages, and endothelial cells, leading to their recruitment, retention, activation, and differentiation. Both cell surface receptor interactions and secreted mediators are important in this process. T cell-fibroblast interactions include T cell recruitment and retention by fibroblast-secreted chemokines such as CXCL12, CCL5, and CX3CL1 (fractalkine). In addition, fibroblasts may activate T cells through antigen presentation, co-stimulatory receptors (e.g., CD40, ICAM-1), and cytokine secretion. Fibroblast cytokines such as IL-6 and IL-15 may be particularly important for differentiation of the Th17 T cell subset, and secretion of IFN-β supports T cell survival. Fibroblasts, in turn, are activated by these cell surface interactions and by T cell cytokines, including IL-17 and IFN-γ. B cells are similarly recruited and retained through fibroblast secretion of chemokines such as CXCL12 and CXCL13 and through cell surface adhesion interactions (e.g., VLA-4 and VCAM-1). Critical survival and differentiation signals are maintained through fibroblast secretion of BAFF (Blys) and APRIL. Neutrophils and monocyte/macrophage lineage cells are also recruited by fibroblast chemokine production. Macrophages, in turn, help activate synovial sublining fibroblasts through the production of cytokines such as IL-1 and TNF. Finally, synovial sublining fibroblasts promote angiogenesis through the production of proangiogenic factors such as VEGF and PDGF and may help direct endothelial recruitment of inflammatory cells through secretion of cytokines such as IL-6. **C**, Pannus tissue, an extension of the hyperplastic synovial lining consisting of both activated MLCs and FLS, actively degrades both cartilage and bone through production of matrix-degrading enzymes such as MMPs and cathepsins. In addition, fibroblasts and T cells secrete RANKL, which promotes osteoclast differentiation and activation, leading to bone erosions. Furthermore, production of DKK-1 inhibits Wnt signaling pathways, which normally promote anabolic osteoblast activity, preventing repair of bone erosions. CD40L, CD40 ligand; DKK-1, dickkopf-1; FGF, fibroblast growth factor; ICAM-1, intercellular adhesion molecule-1; IFN-γ, interferon-γ; IL, interleukin; MHC II, major histocompatibility complex type II; MMPs, matrix metalloproteinases; PDGF, platelet-derived growth factor; RANKL, receptor activator of nuclear factor κB ligand; TCR, T cell receptor; TNF, tumor necrosis factor; VCAM-1, vascular cell adhesion molecule-1; VEGF, vascular endothelial growth factor; VLA-4, very late antigen-4.

interferon is not likely to be a successful therapy for RA patients, a prediction that has been borne out in clinical trials.⁸¹ It is likely that this mechanism of stromal cell-induced leukocyte survival occurs in many chronic inflammatory conditions in which T cells accumulate. Not surprisingly, other leukocyte subpopulations have been shown to derive support from stromal cells. Although fibroblast support for T cell and B cell survival exhibits site-specific properties, neutrophil survival is dependent on prior cytokine activation of fibroblasts and shows no differences between fibroblasts taken from different anatomic sites.⁷² Plasma cells are, of course, rescued from apoptosis within the bone marrow stem cell niche,⁸² but mast cells of the gut are rescued by intestinal fibroblasts,⁸³ whereas dermal fibroblasts maintain Langerhans-like cells in the skin.⁸⁴

Fibroblast-Mediated Retention of Leukocytes in Tissue

Although inhibition of T cell death by stromal cells at sites of chronic inflammation contributes to T cell accumulation, it is unlikely to be the only mechanism because lymphocytes should be able to leave the inflamed tissue during the resolution of inflammation, even if their death is inhibited. A number of studies have recently reported that the synovial microenvironment contributes directly to the inappropriate retention of T cells within the joint, by an active chemokine-dependent process. The presence of high levels of inflammatory chemokines, produced by stromal cells, is a characteristic of environments such as the rheumatoid synovium. However, recent data suggest that paradoxically constitutive chemokines, which are involved in the recruitment of lymphocytes to secondary lymphoid tissues, are ectopically expressed in immune-mediated inflammatory diseases. The constitutive chemokine CXCL12 (SDF-1) and its receptor CXCR4 emerged as unexpected but crucial players in the accumulation of T lymphocytes within the rheumatoid synovial microenvironment. This chemokine-receptor pair plays an important role, both in the constitutive traffic of lymphocytes and in the recruitment and retention of hemopoietic cells within the bone marrow. Unexpectedly, CD45RO⁺ T lymphocytes in the rheumatoid synovium were found to express CXCR4 receptors at high levels in the rheumatoid synovium. The CXCR4 ligand CXCL12 was highly expressed on endothelial cells at the sites of T cell accumulation.^{85,86} In addition, stromal cell-derived TGF- β is responsible for upregulation of CXCR4 receptors on T cells in the synovium.⁸⁵ Evidence also suggests that the stability of lymphocyte infiltrates is reinforced by a positive feedback loop, whereby tissue CXCL12 promotes CD40 ligand expression on T cells, which in turn stimulates further CXCL12 production by CD40-expressing synovial fibroblasts. Furthermore, levels of CXCL12 secreted by synovial fibroblasts have recently been shown to be controlled in part by T cell-derived IL-17.⁸⁷

Therefore clear evidence supports the hypothesis that aberrant ectopic expression of constitutive chemokines such as CXCL12, CCL19, and CCL21 by synovial stromal cells contributes to the retention of T cells within the RA synovium.

Other cell constituents of the rheumatoid inflammatory infiltrate may be affected by the CXCL12/CXCR4 axis.

Blades and colleagues⁸⁸ have shown increased expression of CXCL12/CXCR4 by monocyte/macrophage cells in RA compared with osteoarthritis. In addition, using implanted human synovial tissue in SCID mice, they demonstrated that monocytes are recruited into transplanted synovial tissue by CXCL12.⁸⁸ Contact-mediated B cell survival induced by synovial fibroblasts has also been shown to depend on CXCL12, BAFF/BLyS, and CD106 (VCAM-1)-dependent mechanisms that are independent of TNF.^{51,89} Overexpression of CXCL12 has also been identified as a distinct feature of RA, as opposed to osteoarthritis synovia, using cDNA arrays. Data validating these findings *in vivo* have come from a collagen-induced arthritis model of RA in DBA/1 (interferon- γ receptor deficient) mice, where administration of the specific CXCR4 antagonist AMD3100 significantly ameliorated disease severity.⁹⁰ In another murine collagen-induced arthritis model the small molecule CXCR4 antagonist 4F-benzoyl-TN14003 ameliorated clinical severity and suppressed delayed-type hypersensitivity (DTH) responses.⁹¹ The CXCL12/CXCR4 constitutive chemokine pair therefore seems to play an important role in lymphocyte retention in RA.

These experiments demonstrate that understanding the behavior of fibroblasts and leukocytes within microenvironments necessarily requires that we model the interactions of all the cellular populations concerned. An elegant example of this approach *in vitro* is the work of Lally and Smith⁹², who developed a flow-based model of cellular recruitment to the rheumatoid synovium. Co-culturing fibroblasts from skin and RA synovial membrane with endothelial cells showed that IL-6 released from synovial (but not skin) fibroblasts was able to induce production of chemokines and adhesion molecules, resulting in greater neutrophil recruitment by synovial fibroblasts. Subsequent work interrogating the system using low-density gene arrays demonstrated that the effect of neutrophil-attracting chemokines such as CXCL5 released from synovial fibroblasts was dependent on the function of the chemokine transporter molecule DARC (Duffy antigen receptor for chemokines), which was also induced by fibroblast-to-endothelial cell co-culture.⁹²

Constitutive Chemokines and Lymphoid Neogenesis

RA is one of a number of inflammatory diseases in which the organization of the inflammatory infiltrate shares characteristics of lymphoid tissue. Follicular hyperplasia with germinal center formation can occur in autoimmune thyroid disease, myasthenia gravis, Sjögren's disease, and RA and may occur during infection with *Helicobacter pylori* and *Borrelia burgdorferi*. The lymphoid infiltrates in the rheumatoid synovium can be divided into at least three distinct histologic groupings, varying from diffuse lymphocyte infiltrates through organized lymphoid aggregates to clear germinal center reactions. Moreover, there is conflicting evidence that such distinct histologic types correlate with other serum indicators of disease activity. This form of inflammatory lymphoid neogenesis relies on inappropriate but highly organized temporal and spatial expression by fibroblasts of the constitutive chemokines, particularly CXCL13 and CCL21, which are required for physiologic lymphoid

organogenesis. The elegant choreography of lymphocyte-stromal interactions within lymph nodes is organized by expression of adhesive and chemotactic cues in overlapping and combinatorial fashions. Once they have encountered new antigen, dendritic cells (DCs) specialized in the presentation of antigen to lymphocytes undergo a process of maturation under the local influence of inflammatory cytokines and bacterial and viral products. As a result, inflammatory chemokine receptors are downregulated and upregulation of the constitutive receptors CCR4, CCR7, and CXCR4 occurs, causing DCs to migrate into local draining lymphatics and thereby into peripheral lymph nodes. Trafficking of B and T cells is regulated by CXCL13 (BCA-1, B cell-attracting chemokine 1), its receptor CXCR5, and CCL21 and CCL19 (EBL-1-ligand chemokine, ELC), which are both CCR7 agonists. Within the lymph node CXCR5-bearing B cells are attracted to follicular areas, whereas T cells and DCs are maintained within parafollicular zones by local expression of CCL21 and CCL19. Some T cells that have been successfully presented with their cognate antigen by DCs then upregulate CXCR5, allowing them to migrate toward and interact with B cells.⁹³⁻⁹⁵

The genesis of lymphoid follicular structures in diseases such as diabetes and RA appears to rely on expression of such constitutive chemokines, in association with the lymphotoxins alpha and beta (LT- α and LT- β) and TNF.⁹⁶ In this context it is important to note that transgenic animals overexpressing the TNF gene display increased formation of focal lymphoid aggregates and develop a chronic arthritis similar to RA.⁹⁷ Clearly, one of the many mechanisms of action of anti-TNF therapy may be the dissolution of such aggregates. In transgenic mouse models, expression of CXCL13 in the pancreatic islets was sufficient for the development of T- and B-cell clusters, but because they lacked follicular dendritic cells, it was not sufficient for true germinal center formation.⁹⁸ CCL21 does appear to be sufficient in some cases for lymph node formation; murine pancreatic islet models have demonstrated formation of lymph node-like structures in the presence of CCL21, and lymphoid infiltrates in response to CCL19 expression. The degree of lymphoid organization seen in the rheumatoid synovium has been shown to correlate with expression of the chemokines CCL21 and CXCL13, although these chemokines are also associated with less organized lymphoid aggregates.⁹⁹ Expression of CCL21 is restricted to a population of perivascular fibroblastic reticular cells with common phenotype and function in secondary lymphoid and inflammatory aggregate tissues.¹⁰⁰ CXCR5 is overexpressed in the rheumatoid synovium, consistent with a role in recruitment and positioning of B and T lymphocytes within lymphoid aggregates of the RA synovium. It therefore seems likely that expression of lymphoid-constitutive chemokines contributes significantly to the entry, local organization, and exit of lymphocytes in the RA synovium. It also seems that the ectopic expression of chemokines is a general characteristic of a number of chronic rheumatic conditions because another B cell-attracting chemokine CXCL13 (BCA-1) is inappropriately expressed by fibroblasts in the salivary glands of patients with Sjogren's syndrome.¹⁰¹ Interestingly, the ectopic lymphoid structures seen in RA are capable of appropriate secondary lymphoid tissue structures including

the production of class-switched high-affinity antibody production, as evidenced by the expression of activation-induced cytidine deaminase (AID), the enzyme required for somatic hypermutation and class-switch recombination (CSR) of Ig genes.¹⁰² CXCR3 expressing plasma cells are also present in the rheumatoid synovium, and their recruitment is once more supported by ectopic production of the CXCR3 ligand CXCL9 by fibroblasts, particularly in the sublining region where aggregates are located.¹⁰³

Role of Fibroblast Subsets in Disease

It is possible that the various potential sources of expanded populations of synovial fibroblasts discussed earlier may correspond with functionally diverse fibroblast lineages and subpopulations. Kasperkovitz and collaborators⁵ showed using microarray analysis that the transcriptional profile of RA synovial fibroblasts clustered into two broad groups representing "high" (myofibroblastic) and "low" (growth factor producing) populations. These clusters were shown to be representative of the heterogeneity and of the degree of inflammation in the tissue of origin, suggesting that transcriptionally and functionally distinct populations of fibroblasts exist in joints.⁵ For example, some CD248⁺ cells may correspond with a pluripotential, stem cell-like population of pericytic cells lying in close apposition to endothelial cells, which provide a supply of new stromal cells during inflammation.¹⁰⁴ Interestingly, deletion or removal of the intracellular portion of CD248 can reduce stromal cell accumulation and ameliorate models of arthritis such as murine collagen antibody-induced arthritis (CAIA).¹⁰⁵ Furthermore, the prevailing conditions of hypoxia within the rheumatoid synovium may enhance expression of CD248, which is regulated by hypoxia-inducible factor-2 (HIF-2) binding to a hypoxia response element, and which in turn participates in angiogenesis.¹⁰⁶ Whether such markers remain associated with functionally distinct subpopulations or simply contribute to a larger local pool of multipotential mesenchymal precursors is as yet unknown, but the discovery of markers apparently linked to function has provided the tools with which such questions can be answered. The results of studies demonstrating the association of stromal subpopulations with disease outcomes and response to therapy are eagerly awaited, as are the first attempts to target stromal markers therapeutically. The other group of markers that has been associated with synovial fibroblasts has come from the field of oncology.

Lessons Learned from Cancer

Alongside the field of inflammation, oncology has also been experiencing a surge in interest in the biology of fibroblasts and stromal cells, as well as the mechanisms by which they interact with primary transformed tumor cells.¹⁰⁷ A number of important cytokines that contribute to cancerous transformation of healthy cells by so-called cancer-associated fibroblasts have been described. These include hepatocyte growth factor (HGF) and TGF- β . Crucially, tumor-associated fibroblasts appear able to transform normal, in addition to premalignant, cells.¹⁰⁷ The importance of tumor-associated fibroblasts, termed cancer-associated fibroblasts (CAFs), has been demonstrated in breast cancer

where human breast cancer implants were unable to grow successfully when implanted into mice without their co-administration with human tumor-derived fibroblasts.¹⁰⁸ Intriguingly, similar molecular signals have been implicated in the predilection for cancer cells to metastasize to certain sites. In particular, the ectopic expression and function of the CXCL12/CXCR4 ligand-receptor pair, in a manner reminiscent of RA, has been implicated in the persistence and tissue tropism of metastatic cells in breast cancer. Tumor-associated fibroblasts secrete CXCL12, resulting in increased promotion of carcinoma cell proliferation, migration, and invasion compared with control fibroblasts but also leading to recruitment of endothelial cell precursors.^{109,110}

Furthermore, molecules that mark fibroblast subpopulations in the joint are associated with active, invasive cancer. These include the expression of tumor-associated stromal markers such as fibroblast activation protein (FAP),^{12,13} galectin-3,^{111,112} and S100A4.¹¹³ Interestingly, galectin-3 has been shown to be subject to epigenetic regulation.^{112,114} Both gp38 and CD248 are also heavily implicated in tumor progression.^{9,115}

These similarities between RA synovial fibroblasts and cancer-associated fibroblasts overlap with observations that the persistent phenotype of RA synovial fibroblasts itself includes elements normally associated with “transformed” cells. These include loss of density and anchorage limitation for growth, which usually curtails in vitro fibroblast culture, firm adherence to ECM components of cartilage, and the invasiveness that is most aptly demonstrated in the chimeric SCID mouse model. Another defining characteristic of RA synovial fibroblasts that helps to explain their phenotype is dysregulation of proto-oncogenes and tumor suppressor genes. Once again, epigenetic regulation is likely to underlie this phenotype. However, the precise mechanisms maintaining the persistent phenotype at a whole genome level are yet to be elucidated. Furthermore, RA is a systemic disease involving multiple joints; therefore whether the fibroblast phenotype results from a global change in fibroblast gene expression or whether the phenotype is locally imprinted by exposure to a characteristic cytokine, matrix, and cellular milieu is yet to be established. Recent data now appear to confirm that human RA synovial fibroblasts within the SCID mouse model may travel systemically through lymphatics and the bloodstream to unpopulated samples of cartilage and then invade.¹⁹ Therefore at least one possibility is that locally imprinted, “activated” fibroblasts may export destructive arthritis to joints where mild injury or immune response has occurred over time. In the cancer field, the concept of tumor stroma “normalization” has now become an accepted aspect of new oncology therapies. Clinical studies of angiogenesis inhibitors and antibodies against ECM components such as tenascin have been favorable, while inhibitors of MMPs, overexpression of TIMPs, and blockade of integrin signaling have all shown promise in preclinical trials.¹¹⁶ Results of studies examining the interactions between endothelial cells and their associated pericytes underlie the importance of targeting the stroma as a whole. Bergers and colleagues¹¹⁷ have shown that endothelial cells release PDGF, which induces VEGF production from pericytes leading to bidirectional conversations between the two cell types. Interrupting these

conversations by using PDGF inhibitors proved to be more effective therapy than using VEGF inhibitors alone. Interestingly, although VEGF inhibitors lost their inhibitory effect in later-stage tumors, targeting of the pericytes helped even late-stage tumors to regress.¹¹⁷ The authors have subsequently shown that pericyte precursors are partly recruited from the bone marrow to tumor perivascular sites.¹¹⁸

SUMMARY

Fibroblasts are structural mesenchymal cells that form the cellular infrastructure for most internal organs, as well as for bordering membranes such as the synovial membrane. They are prominently involved in the deposition and resorption of the ECM and thus are responsible for maintaining tissue homeostasis. However, fibroblasts are far more than structural, passively responding cells that build the “backbone” for organ-specific function. Rather, they are sensitive to environmental changes. They react in a specific manner to a variety of stimuli and are capable of actively influencing not only the composition of the ECM but also the cellular composition of tissues and barrier membranes. Under inflammatory disease conditions, fibroblasts act as organ-specific, innate immune system sentinel cells and are involved in the progression of organ damage, as well as in the switch from acute resolving to chronic persisting inflammation. We now know that functionally distinct fibroblast subsets exist and can be identified with new markers in order to understand better mechanisms of developmental patterning, wound healing, and persistent inflammatory responses, which appear to depend in large part on epigenetic modifications. This notion is particularly true for fibroblast-like synoviocytes, which play a critical role in the pathogenesis of RA and possess a characteristic, invasive, and activated phenotype. In addition to contributing to the recruitment of inflammatory cells to the joint, they modulate the survival and behavior of these cells and are, in turn, regulated by the newly recruited cells. More importantly, fibroblast-like synoviocytes are crucial components in the hyperplastic lining layer and in cartilage destruction. New data raise the possibility of epigenetically programmed aggressive cells exporting arthritis from inflamed to uninfamed joints in the early stages of arthritis, but at the same time offering the possibility of specifically targeting stromal subpopulations of choice.

KEY POINTS

Mast cells arise in the bone marrow, circulate as immature precursors, and develop into functional mast cells upon entering peripheral tissues.

The phenotype of mast cells is diverse, plastic, and governed by signals from lymphocytes, fibroblasts, and other elements of the microenvironment.

In healthy tissues, mast cells serve as immunologic sentinels and participate in both innate and adaptive immune responses to bacteria and parasites.

Mast cells accumulate in injured and inflamed tissue, where they may amplify or suppress inflammation.

Mast cells have been implicated in multiple autoimmune diseases, including inflammatory arthritis.

Although the mast cell is best known for its role in allergy and anaphylaxis, the immune function of this bone marrow-derived lineage extends well beyond its participation in immunoglobulin (Ig)E-driven disease. Mast cells are resident broadly in vascularized tissues but cluster near interfaces with the external world, in the linings of vulnerable body cavities, and near blood vessels and nerves. In these locations, mast cells serve as immune sentinels, equipped with an array of pathogen receptors and an armamentarium of mediators capable of rapidly recruiting immune effector cells. Mast cells also accumulate at sites of tissue injury and chronic inflammation, although their role in such locations remains uncertain. Other functions for this lineage, conserved by evolution for over 500 million years, continue to be defined.

Circumstantial and experimental evidence implicates mast cells in the pathogenesis of rheumatic diseases. Mast cells reside constitutively in the normal synovium and are found in large numbers in inflamed synovial tissue; mast cell mediators are identified in inflammatory joint fluid. Moreover, models have indicated that mast cells may contribute importantly to the pathogenesis of experimental arthritis. Mast cells have also been implicated in other autoimmune conditions, including multiple sclerosis, bullous pemphigoid, and systemic sclerosis. This chapter reviews the basic biology of mast cells and their potential role in human inflammatory diseases.

BASIC BIOLOGY OF MAST CELLS

Development and Tissue Distribution

Mast cells are distinctive in appearance. Ranging in size from 10 to 60 μM and with a centrally located round or oval nucleus, their abundant cytoplasm is filled with multiple small granules. They were named *Mastzellen* in 1878 by the German pathologist Paul Ehrlich, who believed incorrectly that they were overfed connective tissue cells (*mästen*, German, “to feed or fatten an animal”).¹ Electron microscopy reveals that the plasma membrane of mast cells exhibits multiple thin cytoplasmic extensions, providing a broad interface with surrounding tissue (Figure 16-1A). The tissue distribution of mast cells is extensive; within tissue, mast cells tend to cluster around blood vessels and nerves, and near epithelial and mucosal surfaces. They are also found in the lining of vulnerable body cavities such as the peritoneum and the diarthrodial joint. Given this localization, mast cells are among the first immune cells to encounter pathogens invading into tissue from the external world or via the bloodstream, consistent with their role as immune sentinel cells.²

Mast cells are of hematopoietic origin, arising in the bone marrow and depositing in tissues after migrating through the bloodstream^{3,4} (Figure 16-2). Unlike most other myeloid cells, such as monocytes and neutrophils, mast cells do not terminally differentiate in the bone marrow but rather circulate as committed progenitors, bearing the surface signature $\text{CD34}^+/\text{c-kit}^+/\text{CD13}^+$.⁵ Further developmental details have been worked out most extensively in the mouse. Upon entering the tissues, murine mast cells may mature into classic granulated cells or may remain as ungranulated progenitors, awaiting local signals to differentiate fully. Comparison of murine lung and intestine has demonstrated that these tissues use distinct pathways to regulate the constitutive and inducible recruitment of mast cell progenitors, illustrating that mast cell homing is a precisely controlled process.⁶ Tissue homing is modulated prominently by lymphocytes, including regulatory T cells (Tregs).⁷

Once resident in tissues, mast cells may live for many months.⁸ Unlike other myeloid lineage cells such as macrophages and neutrophils, mature mast cells remain capable of mitotic division, although recruitment of circulating progenitors appears to greatly exceed local replication as a pathway to expand the number of mast cells in a tissue.⁹ Mechanisms of reducing mast cell numbers include apoptosis, demonstrated in tissue mast cells deprived of the cytokine stem cell factor, a critical survival signal for mast cells.^{10,11} Under certain conditions, mast cells may emigrate

Figure 16-1 Mast cell morphology. **A**, Intact mast cell. **B**, Mast cell that has undergone anaphylactic degranulation; note how fusion of intracellular granules has resulted in the formation of a labyrinth of interconnected channels by which granule contents may be expelled from the cell. Arrows indicate remaining granules. N, nucleus. (Images courtesy Dr. A. Dvorak, Beth Israel Deaconess Medical Center, Boston, Mass. Figure 16-2 Mast cell origin and differentiation. Mast cells arise in the bone marrow, circulate as committed progenitors, and differentiate into mature mast cells upon entering tissue. Human mast cells may be classified on the basis of granule proteases into tryptase+ mast cells (MC_T) and tryptase+/chymase+ mast cells (MC_{TC}), with characteristic tissue localization and mediator production. SCF, stem cell factor. (Adapted from Gurish MF, Austen KF: The diverse roles of mast cells, *J Exp Med* 194:F1–F5, 2001. Illustration by Steven Moskowitz.)

via the lymphatics, appearing in draining lymph nodes much in the manner of dendritic cells.¹²

Mast Cell Heterogeneity: Common Progenitor, Multiple Subsets, and Phenotypic Plasticity

Although all types of mast cells derive from a common progenitor lineage, the phenotype of fully differentiated tissue mast cells is heterogeneous. Human mast cells are conventionally divided into two broad classes based on the protease content of their granules (see Figure 16-2).¹³ MC_{TC} display rounded granules containing the enzymes tryptase and chymase; the smaller and more irregularly shaped granules of MC_T contain tryptase but not chymase.¹⁴ MC_{TC} also express other proteases, including carboxypeptidase and cathepsin G. MC_C cells bearing only chymase have been reported but are controversial. These subtypes differ in tissue distribution. MC_{TC} tend to be found in connective tissue, such as normal skin, muscle, intestinal submucosa, and synovium; MC_T predominate in mucosal sites, including the lining of the gut and respiratory tract, although in fact both are present in many locations.^{15,16} Beyond protease signature, other differences between these subsets include their profiles of cytokine elaboration and cell surface receptor expression; however, tissue-specific phenotypic differences are noted within each type.

The relationship between MC_{TC} and MC_T mast cells is controversial. Are they committed subsets, akin to CD4 and CD8 lymphocytes, or functional states that mast cells assume under the influence of the microenvironment? In

the mouse, where an analogous distinction exists between connective tissue mast cells (CTMCs) and mucosal mast cells (MMC), evidence for phenotypic plasticity is strong. Both in culture and in vivo, single CTMCs may differentiate into (or give rise to) MMCs and vice versa.^{17,18} Mast cells with intermediate protease expression are found, and serial observations suggest that exposure to an inflammatory stimulus can induce progressive change from one class to another, although whether this occurs at a single-cell level has not been definitively established.¹⁹ Similarly, in murine and human mastocytosis, clonally expanded mast cells display divergent phenotypes depending on the tissue of residence.^{20,21} In aggregate, these data favor the hypothesis that mast cells assume a particular phenotype under the control of local signals but can change radically if conditions change.

Stem Cell Factor

One of the most important signals from tissue to local mast cells is stem cell factor (SCF).¹⁰ The receptor for SCF, c-kit, is expressed widely on hematopoietic lineages early in differentiation, but among mature lineages, mast cells are one of the few cell types that express c-kit at a high level. Stimulation of mast cells by SCF promotes maturation and phenotypic differentiation, blocks apoptosis, and induces chemotaxis. It may also activate mast cells directly to release mediators. In both mouse and humans, SCF remains an irreplaceable survival signal for tissue mast cells. Accordingly, mice with defects in SCF or c-kit are strikingly deficient in mature tissue mast cells (examples include W/W^v, Sl/Sl^d, and W^{sash} strains). Similarly, clonal mast cells obtained from patients with systemic mastocytosis commonly exhibit activating mutations in *c-kit*.²²

SCF occurs in two alternate forms resulting from differential mRNA splicing: soluble and membrane bound.¹⁰ The importance of this latter form is clear from Sl/Sl^d mice, which lack only the membrane-bound isoform yet exhibit very few tissue mast cells.²³ SCF is synthesized by multiple lineages, including mast cells themselves. Expression by fibroblasts is likely especially important, given the intimate physical contacts observed between fibroblasts and mast cells in situ. Rodent mast cells co-cultured with fibroblasts demonstrate enhanced survival, connective tissue phenotypic differentiation, and heightened capacity to elaborate proinflammatory eicosanoids—effects mediated at least in part by direct contact, including interactions between SCF and c-kit.^{24,25} The extent of similar regulation in human mast cells is uncertain.²⁶ Expression of SCF has also been documented on other lineages, including macrophages, vascular endothelium, and airway epithelium, and is likely a critical pathway by which tissues modulate the local mast cell population.

T Lymphocytes and Other Cells

It is interesting to note that T lymphocytes exert a profound effect on mast cell phenotype. SCID mice lacking T cells fail to develop mucosal mast cells, a defect that may be corrected by T cell engraftment.²⁷ An analogous observation has been made in humans deficient in T cells as the result of congenital immunodeficiency or acquired

immunodeficiency syndrome (AIDS). Intestinal biopsy in these patients shows that mucosal mast cells (MC_T) are strikingly reduced, but connective tissue (MC_{TC}) mast cells are present in normal numbers.²⁸ The pathways by which T cells exert this striking effect are not defined, although it is clear that T cell cytokines such as interleukin (IL)-3, IL-4, IL-6, IL-9, and transforming growth factor (TGF)- β may have profound effects on the phenotype of mast cells matured in culture.²⁹⁻³¹ By contrast, interferon (IFN)- γ inhibits mast cell proliferation and may induce apoptosis. These observations imply that cells recruited to an inflamed tissue may profoundly impact the phenotype of local mast cells. The rheumatoid synovium may well exemplify this phenomenon: Normally populated by MC_{TC} mast cells, large numbers of MC_T are identified in the inflamed synovium, typically in regions rich in infiltrating leukocytes, while MC_{TC} reside in deeper, more fibrotic areas of the joint.³² It is interesting to note that Treg cells can also directly impact mast cell function, including receptor expression and degranulation.^{33,34}

Other cells beyond T cells may potentially interact with mast cells in the tissues. In particular, fibroblasts and mast cells commonly demonstrate close physical interactions.³⁵ Beyond SCF, fibroblasts elaborate cytokines such as the IL-1 family member IL-33, which can exert determinative effects on mast cell protease expression and effector phenotype.^{36,37}

Different Functions for MC_T and MC_{TC} Mast Cells?

The preservation of distinct types of mast cells in multiple species implies distinct and nonoverlapping roles for these subtypes. However, our understanding of functional differences between MC_T and MC_{TC} remains limited. One hypothesis is that MC_T play a proinflammatory role and MC_{TC} specialize in matrix remodeling.³⁸ This hypothesis makes sense of (1) the promotion of MC_T development by T cells patrolling the tissues; (2) the partitioning of MC_T and MC_{TC} mast cells to inflamed and fibrotic areas respectively; and (3) the preferential expression of the proinflammatory mediators IL-5 and IL-6 by MC_T and the profibrotic IL-4 by MC_{TC}.³⁹ Not all observations fit comfortably into this dichotomy, however. For example, the potently proinflammatory anaphylatoxin receptor C5aR (CD88) is expressed on MC_{TC} but not on MC_T.⁴⁰ Ultimately, too little is known about the actual functional importance of these subsets to permit firm conclusions.

Mast Cell Activation

IgE

The canonical pathway to mast cell activation is via IgE and its receptor Fc ϵ RI. With a K_a of 10^{10} /M, this receptor is essentially constantly saturated with IgE at typical serum concentrations.⁴¹ Such binding not only sensitizes mast cells to the target antigen but also helps to promote mast cell survival and, in some cases, cytokine production.^{42,43} Cross-linking of Fc ϵ RI-bound IgE by multivalent antigen induces a brisk and vigorous response. Within minutes, granules within the mast cell fuse together and with the surface membrane create a set of labyrinthine channels that allow

rapid release of granule contents (see Figure 16-1B).⁴⁴ This compound exocytosis event, termed *anaphylactic degranulation*, is followed within minutes by the elaboration of eicosanoids newly synthesized from arachidonic acid cleaved from internal membrane lipids. Finally, signals transduced via FcεRI induce the transcription of new genes and the elaboration of a wide range of chemokines and cytokines (Figure 16-3). Upon termination of the stimulation event, the surface membrane closes over the granule-formed channels; these subsequently bud off within the cytoplasm, re-creating discrete granules using the original membranes.⁴⁴ These granules become recharged with mediators through a process that occurs gradually over days to weeks.⁴⁵

IgG and Immune Complexes

IgE is only one among many pathways of mast cell activation. One key trigger for mast cell activation in both human and mouse is IgG, acting via receptors for the Fc portion of IgG (FcγR). The importance of this pathway was demonstrated first in mice rendered genetically deficient in IgE. Contrary to expectations, these animals remained susceptible to anaphylaxis mediated through IgG and the low-affinity IgG receptor FcγRIII.^{46,47} The human counterpart of this receptor, FcγRIIa, is equally capable of inducing

activation of human mast cells.⁴⁸ Human mast cells exposed to IFN-γ may also be induced to express the high-affinity IgG receptor FcγRI, rendering them susceptible to IgG-mediated activation, although expression of this receptor in vivo has not been shown.⁴⁹

These IgG receptors contribute to involvement of mast cells in IgG-driven diseases. Thus, in the mouse, mast cells participate in IgG-mediated immune complex peritonitis, the cutaneous Arthus reaction, and experimental murine bullous pemphigoid.⁵⁰⁻⁵² Activation via Fc receptors also mediates mast cell participation in antibody-mediated murine arthritis.^{53,54}

Soluble Mediators and Cell-Cell Contact

Mast cells may coordinate with immune and nonimmune lineages via mechanisms beyond antibody response, including soluble mediators and surface receptors. Examples of such signals include the cytokine tumor necrosis factor (TNF) and the neurogenic peptide substance P, which can induce mast cell degranulation.^{55,56} Physical contact with other cells can also induce mast cell activation. For example, CD30 on lymphocytes can interact with CD30L on mast cells to induce the production of a range of chemokines.⁵⁷ It is interesting to note that ligation of CD30L does not induce the release of granule contents or lipid mediators, illustrating the selectivity of response of which mast cells are capable.

Danger and Injury

Mast cells are equipped to recognize danger in the absence of guidance from other lineages via a range of pathogen receptors, including multiple Toll-like receptors (TLRs) and CD48, a surface protein recognizing the fimbrial antigen FimH.⁵⁸ These receptors are implicated in the response of mast cells to pathogens.⁵⁹ Mast cells may also be activated through complement, including the anaphylatoxins C3a and C5a.^{54,56} Finally, mast cells can respond directly to physical stimuli such as trauma, temperature, and osmotic stress.⁶⁰ Together, these receptors enable mast cell involvement in a broad range of immune and nonimmune processes.

Inhibitory Signals for Mast Cells

As with other immune lineages, mast cells are subject to both negative and positive regulation. Examples of inhibitory receptors on the surface of mast cells include the IgG receptor FcγRIIb and the integrin-binding immunoglobulin superfamily member gp49b1. The importance of these receptors is demonstrated in genetically deficient animals. Mice lacking FcγRIIb demonstrate a striking propensity to activation via both IgG and IgE (which bind with low affinity to FcγRIIb as well as to FcεRI),^{61,62} but gp49b1-null mice are unusually susceptible to IgE-mediated anaphylaxis.⁶³ Of note, no human orthologue of gp49b1 is known, thus the relevance of this pathway in modulating MC activity in humans remains unclear. Nevertheless, modulating the surface expression of inhibitory receptors serves as an important mechanism for regulation of the activation threshold of mast cells in tissues.⁶⁴

Figure 16-3 Mediator production by human mast cells (partial list). The set of mediators liberated upon activation will vary depending on the state of differentiation of the mast cell and the nature of the stimulus. See Reference 96 for a complete mediator list and references. bFGF, basic fibroblast growth factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; Ig, immunoglobulin; IL, interleukin; LTC₄, leukotriene B₄; MCP-1, monocyte chemoattractant protein-1; M-CSF, macrophage colony-stimulating factor; PAF, platelet-activating factor; PDGF, platelet-derived growth factor; PGD₂, prostaglandin D₂; RANTES, released upon activation, normal T cell expressed and secreted; SCF, stem cell factor; TARC, thymus and activation-regulated chemokine; TGF-β, transforming growth factor-β; TLR, Toll-like receptor; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor.

Mast Cell Mediators

Granule Contents: Proteases, Amines, Proteoglycans, and Cytokines

Mature mast cells package a range of mediators in their granules, ready for immediate release through fusion with the surface membrane. The most abundant of these are the neutral proteases, named for their enzymatic activity at neutral pH, but vasoactive amines, proteoglycans such as heparin, and pre-formed cytokines play distinct roles in the biologic consequences of mast cell degranulation. The release of these mediators is not all or none. In addition to anaphylactic degranulation, mast cells may release only a few granules at a time in a process termed *piecemeal degranulation*.⁶⁵ Further, mast cells can release one type of granule but not another.⁶⁶ Alternately, mast cells may be induced to elaborate cytokines and chemokines with no release of granule contents, as illustrated by activation via CD30L.⁵⁷ Thus, although the mast cell is well equipped to release large volumes of pre-formed mediators, it is equally capable of responses tailored to the activating stimulus.

Trypsin. Named for its enzymatic similarity to pancreatic trypsin, trypsin is the most abundant granule protein in human mast cells.⁶⁷ It is an essentially specific marker for mast cells, synthesized in scant amounts by basophils but by no other lineage.⁶⁸ The enzyme found in granules is the β -isomer, which is enzymatically active upon formation of a homotetramer that relies on the scaffolding function of the proteoglycan heparin.⁶⁹ Mast cells also synthesize α -trypsin, a protein incapable of forming homotetramers and so enzymatically inactive. Unlike β -trypsin, the α -isomer is not stored in granules but is constitutively released into the circulation, where its function is unknown. The distinction between trypsin isomers is important for diagnostic reasons: As a marker of degranulation, systemic levels of β -trypsin serve as a marker of recent anaphylaxis.⁷⁰ By contrast, α -trypsin levels reflect total body mast cell load and serve as a useful biomarker in systemic mastocytosis.⁷¹ Trypsin directly cleaves structural proteins such as fibronectin and type IV collagen and enzymatically activates stromelysin, an enzyme responsible for activating collagenase.⁷² Trypsin also promotes hyperplasia and activation of fibroblasts, airway smooth muscle cells, and epithelium. Cleavage of protease-activated receptors such as PAR-2 may contribute to some of these activities,⁷³⁻⁷⁵ although other studies have documented PAR2-independent trypsin activation of mesenchymal cells.⁷⁶ In aggregate, these effects suggest an important role for trypsin in matrix remodeling. A further contribution to the inflammatory milieu is suggested by the capacity of trypsin to promote neutrophil and eosinophil recruitment and to cleave C3, C4, and C5 to generate anaphylatoxins.⁷⁷⁻⁷⁹ It is interesting to note that trypsin can potentially downregulate inflammation by cleaving IgE and IL-6.^{80,81}

Chymase. This chymotrypsin-like neutral protease is found in the MC_{TC} subset of human mast cells, packaged within the same granules as trypsin.¹⁴ Similar to trypsin, chymase can cleave matrix components and activate stromelysin, although it can also activate collagenase directly, suggesting a role in matrix remodeling.⁸² Chymase can influence cytokine function, with the capacity to cleave pro-IL-1 β to generate active cytokine, as well as

to inactivate proinflammatory cytokines such as IL-6 and TNF.^{80,83,84}

Vasoactive Amines. Human mast cells are capable of synthesizing and storing the biogenic amines histamine and serotonin, implicated in vascular leak.⁸⁵ Histamine, by far the more abundant, is a vasoactive amine found in both MC_T and MC_{TC} mast cells, although it is not unique to this lineage. Histamine is involved in the wheal-and-flare response to cutaneous allergen challenge via augmented vascular permeability, transendothelial vesicular transport, and neurogenic vasodilation. These effects are mediated principally via the H1 receptor. Three other histamine surface receptors, H2 through H4, are distributed widely on immune and nonimmune lineages, with effects as diverse as gastric acid secretion, Langerhans cell migration, and B cell proliferation.⁸⁶

Heparin and Chondroitin Sulfate E. These large proteoglycans enable the ordered packing of mediators within human mast cell granules.^{87,88} Negatively charged carbohydrate side chains complex tightly with positively charged proteins, allowing very high concentrations of β -tryptase and other proteases. Heparin, produced exclusively by mast cells, facilitates the activity of tryptase by making possible proteolytic self-activation within the granule and stabilizing the active tetrameric form of this enzyme.⁸⁹ Heparin also has a wide range of effects beyond the mast cell. Heparin is potently angiogenic.⁹⁰ Heparin binding activates antithrombin III, providing the basis for use as an anticoagulant, while inhibiting chemokines and both classical and alternative pathways of complement activation, as well as the function of Treg cells.^{91,92} The physiologic role of these extracellular activities of mast cell-derived heparin is uncertain.

Pre-Formed Cytokines. Mast cells are able to store certain cytokines in their granules for rapid release. The first of these to be documented was TNF.⁹³ In the mouse, this pool of TNF is implicated in the rapid recruitment of neutrophils to the peritoneum during peritonitis.^{50,94} Other cytokines that may be stored in granules include IL-4, IL-16, basic fibroblast growth factor (bFGF), and vascular endothelial growth factor (VEGF).

Newly Synthesized Mediators: Lipid Mediators, Cytokines, Chemokines, and Growth Factors

Beyond pre-formed mediators stored within granules, activated mast cells elaborate a range of mediators that are generated *de novo*. These mediators are released minutes to hours after stimulation, broadening and extending the impact of activated mast cells on surrounding tissues.

Lipid Mediators. Within minutes of activation, mast cells begin to release metabolites of membrane phospholipids. This process is rapid because the relevant enzymes, beginning with phospholipase A2, responsible for harvesting phospholipids from the outer leaflet of the nuclear membrane, are already present in the cytoplasm and need only to be activated through signals mediated by calcium flux and the phosphorylation of intracellular messengers. The hallmark prostaglandin of human mast cells is prostaglandin D₂ (PGD₂), which is capable of inducing bronchoconstriction, vascular leak, and neutrophil recruitment. Smaller quantities of other prostaglandins as well as thromboxane

are also made. Mast cell–derived leukotrienes have similar but generally more potent activity. Leukotriene C₄ (LTC₄) is the major leukotriene species generated by human mast cells; together with its metabolites LTD₄ and LTE₄, it serves as a potent inducer of vascular leak. Smaller quantities of the chemotaxins LTB₄ and platelet-activating factor (PAF) are also generated. The particular profile of lipid mediators produced by mast cells can change with local environmental signals and the resulting state of differentiation. Thus, mast cells from skin generate PGD₂ in excess of LTC₄, and both species are elaborated in roughly equal proportions by mast cells isolated from lung and osteoarthritic synovium.⁹⁵

Cytokines, Chemokines, and Growth Factors. Within hours of activation, mast cells begin to elaborate newly synthesized mediators as the end result of induced gene transcription and translation. The range of such mediators is broad (see Figure 16-3). They include the canonical proinflammatory mediators TNF, IL-1, and IL-6; the Th2 cytokines IL-4, IL-5, IL-10, and IL-13; chemotactic factors including IL-8, MIP-1 α , and regulation upon activation normal T cell expressed and secreted (RANTES); and growth factors for fibroblasts, blood vessels, and other cells such as bFGF, VEGF, and platelet-derived growth factor (PDGF).⁹⁶ As noted earlier, some of these may also be stored pre-formed in granules for rapid release. The panel of mediators generated depends on the state of differentiation as well as the activating signal, and may occur in the absence of degranulation.

ROLE OF MAST CELLS IN HEALTH AND DISEASE

Our understanding of the role of mast cells in health and disease has been aided greatly by the availability of mice

lacking mast cells through defects in the SCF/c-kit axis. Although these mice exhibit multiple phenotypic abnormalities, they are viable, excluding an obligate basal role for mast cells in the structure and function of most tissues. Yet under physiologic stress, such as imposed by experimental models of disease, multiple differences from wild-type become evident. In many cases, these abnormalities may be corrected by engraftment with cultured mast cells,⁹⁷ directly implicating mast cells in a remarkably broad range of disease processes (Table 16-1). Interpretation of such experiments is limited by incomplete physiologic restoration of the mast cell compartment and by residual effects of deficient c-kit signaling in other lineages. However, together with in vitro experiments and careful observation of normal subjects, animal experiments in mast cell–deficient mice have contributed greatly to recent progress in our understanding of mast cell physiology and pathophysiology.

Mast Cells in Allergic Disease: Anaphylaxis, Allergic Disease, and Asthma

Mast cells are the primary mediator of systemic anaphylaxis. This is demonstrated in mast cell–deficient mice, in which resistance to IgE-mediated anaphylaxis may be restored by engraftment with mast cells.⁹⁸ In humans, participation of mast cells in anaphylaxis has been documented through the detection of elevated serum levels of β -tryptase, a specific marker of mast cell degranulation.⁷⁰ Mast cells accumulate in atopic mucosal tissues, where they degranulate upon exposure to antigen and contribute prominently to tissue edema and the overproduction of mucus.⁴¹ Mast cells also accumulate in the asthmatic airway, including within the smooth muscle lining the airways, and have been implicated by human and animal data in airway hyperreactivity and mucosal changes.^{99,100}

Mast cells are implicated in these processes by virtue of phenotypic abnormalities in mast cell–deficient mice, or in mice lacking mast cell–specific mediators. The asterisk (*) indicates that the phenotype has been shown to be reversible by engraftment with cultured mast cells, providing more direct evidence of a role for this lineage.

Mast Cells in Nonallergic Inflammation

Pathogen Defense: Mast Cells as Sentinels of Innate Immunity

The involvement of mast cells in atopic disease is clear but does not explain their remarkable evolutionary conservation. Rather, mast cells must somehow contribute to the survival of the organism. The most probable mechanism by which mast cells convey a survival advantage is defense against infection. This role is reflected in the localization of mast cells near epithelial surfaces, around blood vessels, and in other locations of potential invasion by pathogens.

Mast cells are competent defensive cells against bacteria. They express TLRs and other receptors against bacterial antigens, and upon activation are able to phagocytose bacteria and generate antimicrobial molecules such as cathelicidin.^{101,102} However, given their relatively small numbers, the most important function of mast cells in immune defense is to serve as sentinels, monitoring for early traces of infection and rapidly mobilizing neutrophils and other inflammatory cells when needed. Such a role has been clearly demonstrated in mouse models of bacterial peritonitis, in which mast cell-deficient animals exhibit high mortality. This susceptibility correlates with delayed recruitment of neutrophils via TNF and leukotrienes; both neutrophil influx and survival may be restored by correction of the mast cell deficit, although in severe infection, mast cell TNF may actually contribute to mortality.^{94,103-105} Clearance of bacteria from the lung is delayed in mast cell-deficient mice and can be similarly restored.⁹⁴ Analogous observations have been made in other models of bacterial infection.⁵⁸ Thus, mast cells may play an important role in defense of the host against bacterial infection.

Mast cells are also implicated in the defense against parasites. Mast cell-deficient animals exhibit abnormal clearance of multiple parasites from gut and skin, in a manner promoted by IgE.^{106,107} The mechanism of this defense remains uncertain but may include direct attack upon pathogens, recruitment of inflammatory lineages such as neutrophils and eosinophils, and lysis of tight junctions in the mucosal lining to facilitate the expulsion of helminths.^{106,108,109}

Mast Cells and the Adaptive Immune Response

In addition to recruiting innate effector cells, mast cells mobilize T and B lymphocytes, the adaptive arm of the immune system.⁹⁶ Mast cells may express MHC II, as well as co-stimulatory molecules such as CD80 and CD86, rendering them effective antigen-presenting cells for CD4 T cells. Mast cells can also mobilize and potentiate CD8 T cell responses.¹¹⁰ They may migrate from peripheral tissues to lymph nodes carrying antigen and may contribute to the recruitment of T cells to lymph nodes via mediators such as MIP-1 β and TNF, as well as suppression of Treg responses.^{12,111,112} Indeed, infection-induced lymph node hyperplasia is abrogated in the absence of mast cells. Further, mast cells can recruit CD4 and CD8 effector T cells to peripheral tissues via leukotriene B₄, among other mediators.¹¹³⁻¹¹⁵ Finally, mast cells can contribute to the migration of cutaneous Langerhans cells and other dendritic

cells to lymph nodes via mediators including histamine.¹¹⁶⁻¹¹⁸ By means of the inducible expression of CD40L and cytokines, mast cells may stimulate B cells and induce class switching to IgA or IgE.^{119,120} The physiologic importance of these effects will vary with circumstances. For example, under some conditions delayed-type hypersensitivity responses in skin are mast cell dependent, but under others mast cells appear to play no role.⁹⁶ The potential importance of the mast cell in adaptive immunity is highlighted by the recent demonstration that mast cell activators are effective vaccine adjuvants.¹²¹

Neurogenic Inflammation

In addition to their perivascular localization, mast cells cluster near and even within peripheral nerves. A discrete function for them in these locations has not yet been identified, although the potential for bidirectional neuroimmune interaction is clear. Mast cell mediators such as histamine may directly activate neurons, and mast cells residing near stimulated neurons may be induced to degranulate.¹²² Indeed, vascular leak and neutrophil infiltration arising from infiltration of skin with the neurogenic mediator substance P are mediated by mast cells.^{123,124} Thus neurons may recruit mast cells as local effectors to initiate neurogenic inflammation.

Autoimmune Disease

Reconstitution experiments in mast cell-deficient mice have implicated mast cells in a variety of pathologic conditions (see Table 16-1). These include murine models of autoimmune diseases such as bullous pemphigoid, multiple sclerosis, scleroderma, and inflammatory arthritis. In pemphigoid, mast cells triggered via IgG antibodies against a hemidesmosomal antigen recruit neutrophils that are responsible for blister formation.⁵² The role of mast cells in murine experimental autoimmune encephalomyelitis (EAE) is more complex. Although the resistance of W/W^v mice to EAE corrects with mast cell engraftment, these cells fail to repopulate the brain and spinal cord, indicating that mast cells are not obligate local effector cells in this model.^{125,126} One mechanism for this activity appears to be promotion of the adaptive immune response, because mast cell engraftment into W/W^v animals improves T cell responses to immunization with the inciting myelin antigen.^{127,128} The contribution of mast cells to human scleroderma remains unknown. The participation of mast cells in arthritis is discussed in detail later.

MAST CELLS AS ANTI-INFLAMMATORY CELLS

Within the last few years, it has become evident that mast cells may also help moderate the immune response. One mechanism for this effect is degradation of proinflammatory mediators. Mast cell proteases may cleave and inactivate the cytokines IL-5, IL-6, IL-13, and TNF, as well as endothelin-1 and the anaphylatoxin C3a.^{78,84,129,130} The importance of this activity has been demonstrated in a murine sepsis model, in which mast cells reduced mortality

by restraining excess inflammation in a protease-dependent manner.¹³⁰ More broadly, mast cells are capable of producing mediators such as IL-10 that have immunosuppressive activity; even otherwise proinflammatory mediators such as TNF and granulocyte-macrophage colony-stimulating factor (GM-CSF) can be immunosuppressive under appropriate circumstances.¹³¹ Thus, mast cells promote immunologic tolerance to skin grafts and limit tissue inflammation related to ultraviolet-light injury.^{81,132,133}

MAST CELLS AND CONNECTIVE TISSUE

Wound Healing and Tissue Fibrosis

Mast cells have long been noted to accumulate at the borders of healing wounds.¹³⁴ In normal human subjects undergoing experimental wounding and recurrent biopsies, mast cell numbers increase sixfold by day 10 after initial incision. These mast cells localize preferentially to fibrotic areas of the wound and strongly express IL-4, a cytokine capable of inducing fibroblast proliferation and collagen synthesis.⁹ In vitro studies confirm the stimulatory effects of mast cells on fibroblast growth¹³⁵; candidate fibroblast mitogens in addition to IL-4 include tryptase, histamine, LTC₄, and bFGF. Indeed, mast cell-deficient W/W^v animals exhibit delayed contracture and healing of skin wounds in a manner reparable by local engraftment with cultured mast cells.¹³⁶

Mast cells also accumulate in sites of pathologic fibrosis, including the skin and lungs of patients with scleroderma.^{137,138} Because experimental skin fibrosis proceeds in mast cell-deficient mice with only relatively subtle differences in intensity or kinetics, it is unlikely that mast cells are an obligate effector lineage in human scleroderma, although they may contribute to disease progression.^{139,140}

Bone

Mast cells are also implicated in the remodeling of bone. Mast cells accumulate in sites of healing fracture; under normal circumstances, they may contribute productively to normal bone turnover.^{141,142} However, mast cells accumulate in osteoporotic bone, and systemic osteoporosis is a known complication of systemic mastocytosis.^{143,144} Heparin is a potentially important mediator of bone loss, in that it directly promotes differentiation and activation of osteoclasts.¹⁴⁵ Mast cell products such as IL-1, TNF, and MIP-1 α have similar activity.

Angiogenesis

A final and potentially quite important activity of mast cells on the stroma is the promotion of angiogenesis. Mast cells are not required for development of the normal vasculature, as is evident in the viability of mast cell-deficient mice. However, mast cells cluster at sites of early blood vessel growth in tumors and contribute appreciably to physiologic angiogenesis under certain experimental conditions.^{146,147} Heparin was the first proangiogenic mast cell mediator identified⁹⁰; bFGF and VEGF are other potent stimulators of endothelial migration and proliferation.

MAST CELLS IN ARTHRITIS

The normal synovium is populated by a limited number of mast cells. These cells are not found in the immediate lining layer but rather reside in the synovial sublining, near blood vessels and nerves, constituting almost 3% of cells within 70 μ M of the synovial lumen.¹⁴⁸ In both mice and humans, their phenotype is principally MC_{TC}, similar to mast cells found in most other connective tissue sites.^{32,149} The several-fold increased density of mast cells in the immediate vicinity of the synovial lining, compared with more distant connective tissue, supports the hypothesis that mast cells contribute to surveillance of the articular cavity.³² Extrapolating from the activity of mast cells near other vulnerable body cavities, such as the peritoneum, it is likely that synovial mast cells help to monitor the joint for early evidence of infection.

Under conditions of arthritis, the population of synovial mast cells may expand remarkably (Figure 16-4). More than two-thirds of synovial specimens from patients with rheumatoid arthritis (RA) exhibit abnormal numbers of mast cells, averaging in excess of tenfold above normal.¹⁵⁰ Consistent with these histologic findings, synovial fluid from rheumatoid joints contains appreciable quantities of histamine and tryptase.^{151,152} Unlike the normal joint, in the RA joint both subtypes of mast cells are present in roughly equal numbers; MC_T cells are located nearer to the pannus and infiltrating leukocytes, and MC_{TC} cells cluster in deeper, more fibrotic areas of the synovium.³² Mast cells have been noted near the junction of pannus and cartilage.¹⁵³ Rare mast cells are also identified in synovial fluid.¹⁵⁴ The absence of mitotic figures and of staining for the proliferation antigen Ki-67 in this population suggests that they arise not from local replication but rather by recruitment of circulating progenitors.¹⁵⁵ Although the signals driving this recruitment are unknown, inflammatory cytokines such as TNF enhance expression of the mast cell chemotactic and survival factor SCF on synovial fibroblasts, suggesting one

Figure 16-4 Mast cells in the rheumatoid synovium. Stained red by an antibody against tryptase, mast cells are abundant in this synovial biopsy from a patient with chronic rheumatoid arthritis. Note the proliferation of mast cells in the synovial sublining. mechanism for this dramatic expansion.¹⁵⁶ Indeed, degree of inflammation is the best predictor of the number of mast cells within the joint.^{150,157,158} Incompletely identified factors in RA synovial fluid can potentially promote mast cell differentiation and growth.¹⁵⁹

Hyperplasia of the mast cell population is not specific for rheumatoid arthritis but is observed in a wide range of inflammatory joint disorders (Table 16-2). Expansion is also noted in osteoarthritis (OA), often to densities observed in RA.^{32,155,160,161} The levels of histamine and tryptase in OA synovial fluid are also comparable. It is interesting to note that unlike in RA, expansion in OA results from an increase in the numbers of MC_T mast cells, the subtype generally associated with T cells and inflammation.^{32,162}

Mast Cells in Acute Arthritis: Insights from Animal Models

Recent experimental work in mice has begun to shed light on the role of mast cells in inflammatory arthritis. Several mast cell-deficient strains demonstrate striking resistance to arthritis induced by IgG autoantibodies—a defect that may be repaired by engraftment with cultured mast cells expressing receptors for IgG and C5a.^{53,54,163,164} A number of mechanisms contribute to this arthritogenic activity. First, mast cells induce vascular permeability, facilitating entry of autoantibody into the joint.^{165,166} Second, mast cells release proinflammatory mediators including IL-1 that help to establish inflammation, presumably via effects on endothelium and other local populations such as macrophages and fibroblasts.⁵³ These actions appear to be most critical at the initiation of disease, constituting a “jump start” for acute inflammation within the joint. This function is in line with the activity of mast cells in other models of IgG-mediated disease, such as IgG-mediated immune complex peritonitis, murine bullous pemphigoid, and anaphylaxis. In each of these models, mast cells resident in tissue for the purpose of immune defense become co-opted by autoantibodies to initiate inflammatory pathology (Figure 16-5, top).

Mast Cells in Chronic Arthritis

In contrast to the acute phase of joint inflammation, the contribution of mast cells in the context of established arthritis is less well understood. The sheer numbers of these cells in arthritic synovium implies a substantial role. Taking into account the spectrum of mast cell activity

elsewhere, it is likely that mast cells participate both in the inflammatory process and in the mesenchymal response (Figure 16-5, bottom).¹⁶⁷

An ongoing contribution of mast cells to inflammatory arthritis is suggested by several observations. First, as noted, prominent among infiltrating synovial mast cells are MC_T cells, typically associated elsewhere with the elaboration of cytokines such as IL-6 with documented pathogenic activity in rheumatoid arthritis. Immunofluorescence staining has identified TNF and IL-17 in RA synovial mast cells,^{11,168} and elaboration of other proinflammatory mediators is probable. Second, mast cells from RA but not OA synovium express the receptor for the anaphylatoxin C5a, a mediator readily documented in synovial fluid.¹⁶⁹ Immune complexes within RA joints, and potentially IgE antibodies against citrullinated peptides, provide other candidate pathways to activation of synovial mast cells.^{170,171} Indeed, ultrastructural data support ongoing degranulation of mast cells in the RA synovium.¹⁶² Finally, studies of c-kit inhibition in murine and human arthritis suggest efficacy, although it remains unclear whether these agents functionally antagonize tissue mast cells, and whether such antagonism explains their efficacy.^{172,173}

The effects of mast cells on the established inflammatory synovial infiltrate are difficult to predict. As in acute arthritis, activated mast cells may promote the recruitment and activation of leukocytes. Alternatively, protease cleavage of inflammatory mediators and elaboration of cytokines such as IL-10 and TGF- β could downmodulate inflammation, potentially in concert with regulatory T cells, as has been observed in tolerance of skin grafts in mice.¹³²

Mast cells likely modulate the stromal response to inflammation as well. Expansion and activation of synovial fibroblasts is a key pathogenic process within RA, and the capacity of mast cells to promote such changes is well established. Through interaction with osteoclasts, mast cells could promote both focal erosions and periarticular osteopenia. Mast cell tryptase not only promotes inflammation but can contribute directly to joint injury in an amplifying manner by activating synovial fibroblasts to produce chemokines, or by acting directly on susceptible substrates such as cartilage aggregan.^{76,174-176} Finally, by producing proangiogenic mediators, mast cells may enable growth of the vascular supply required for profound expansion of the thin synovial layer into thick pannus. Confirmation of these roles awaits further experimental data.

CONCLUSIONS

Mast cells are potent immune cells characterized by phenotypic diversity and an extremely broad range of functions in health and disease. In addition to mediating atopic disease, mast cells serve as important sentinels against pathogen invasion. Under certain conditions, it is likely that they also participate in control of the immune response and remodeling of tissue matrix. Aberrant activation of mast cells by autoantibodies and potentially other signals has been identified in a range of inflammatory diseases, including arthritis. Such activation may represent a key pathologic step in the development of tissue inflammation and injury, and could present an interesting target for the development of anti-inflammatory therapies.

Figure 16-5 Potential roles of mast cells in acute and chronic arthritis. In the acute phase of joint inflammation, mast cells may contribute to initiation of arthritis by inducing vascular permeability, recruiting and activating circulating leukocytes, and stimulating local fibroblasts and macrophages. In established arthritis, these activities may be joined by effects on the stroma, including promotion of pannus formation, angiogenesis, fibrosis, and injury to cartilage and bone. Potential anti-inflammatory effects of mast cells are not depicted. The mediators listed are representative and do not constitute a complete list. bFGF, basic fibroblast growth factor; IL, interleukin; LTC₄, leukotriene C₄; MIP, macrophage inflammatory protein; MMP, matrix metalloproteinase; PDGF, platelet-derived growth factor; PMN, polymorphonuclear neutrophil; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor. KEY POINTS

Platelets are small circulating cytoplasmic fragments that play a crucial role in hemostasis.

Platelets release a variety of factors that contribute to inflammation, including chemotactic factors for leukocytes; factors that alter vascular tone and permeability; and transforming growth factor- β , a potent stimulus of fibrosis.

Platelet surface proteins also participate in inflammation by serving as sites for leukocyte adhesion (e.g., P-selectin, glycoprotein Ib α [GPIb α]) or as agonists for counterreceptors on leukocytes (e.g., CD40 ligand, platelet-activating factor).

Platelets have been implicated in the pathogenesis of several rheumatic diseases, including rheumatoid arthritis and systemic lupus erythematosus; in the latter case, they have been particularly implicated in atherothrombotic complications.

The development of antiplatelet agents offers the promise of new therapeutic modalities.

Platelets are small circulating cytoplasmic fragments that play a crucial role in hemostasis. They are produced in the bone marrow by megakaryocytes. Single platelets circulate freely in the bloodstream; after vascular injury, platelets adhere to the subendothelium, resulting in responses that contribute to formation of the hemostatic plug. These responses include aggregation, secretion of bioactive compounds, and production of procoagulant activity. Platelets also secrete soluble factors that contribute to wound repair by altering vascular tone and permeability, promoting cell growth, and stimulating scavenger cells such as monocytes. During the inflammatory response, many of the activities that lead to hemostasis contribute to inflammation.¹ Inflammation initiates clotting, decreasing the activity of natural anticoagulant mechanisms and impairing the fibrinolytic system. Conversely, activated platelets release chemotactic factors that promote leukocyte adhesion, which facilitates their extravasation into inflammatory foci. Platelets secrete a variety of factors that can alter vascular tone and permeability. Last, platelets are a major source of transforming growth factor (TGF)- β , a potent stimulus of fibrosis. Taken together, these activities make platelets contributors to the inflammatory response and to the pathogenesis of systemic rheumatic diseases.²

Platelets

FEDERICO DÍAZ-GONZÁLEZ •
MARK H. GINSBERG

GENERAL CHARACTERISTICS OF PLATELETS

Platelets are the smallest blood cells; they are cytoplasmic fragments derived from their bone marrow precursor, the megakaryocyte. Resting platelets have a smooth disk shape and are $3.6 \pm 0.7 \mu\text{m}$ in diameter. On activation, platelets undergo a shape change, becoming a compact sphere with numerous long dendritic extensions, markedly increasing their surface area. In humans, normal platelet counts range from 150,000/ μL to 450,000/ μL . The main function of platelets is to maintain vascular integrity, thereby playing a crucial role in hemostasis.

The plasma membrane of platelets is a typical lipid bilayer, having an extensive series of complex invaginations termed the *canalicular system*. The role of this surface-connected tubular system seems to be to facilitate the quick release of secreted substances to the extracellular environment. The platelet membrane bears numerous glycoprotein (GP) receptors. Platelet surface phospholipids play an important role in coagulation³ and are a source of arachidonic acid, a precursor of important vasoactive substances such as thromboxane A_2 , a potent vasoconstrictor and platelet-aggregating agent, and of leukotrienes, which can amplify the inflammatory response. Platelet surface GPs are receptors that mediate adhesion to subendothelial tissue and subsequent aggregation to form the hemostatic plug.⁴ The largest GP is termed *I* and the smallest *IX*. The labels *a* and *b* distinguish between two separate electrophoretic bands that initially were considered one (e.g., GPI became GPIa and GPIb). The platelet GPIb-IX-V is an important receptor that binds to von Willebrand factor (vWF) exposed in the subendothelial matrix, causing the attachment of platelets.⁵ Deficiency of any component of the GPIb-IX-V complex or of vWF leads to the congenital bleeding disorders Bernard-Soulier disease (GPIb-IX-V complex)⁶ or von Willebrand disease (vWD),⁷ respectively. vWF, in addition to its important role in hemostasis, has been suggested to promote inflammation, facilitating neutrophil diapedesis by destabilization of the endothelial barrier.⁸

ADAMTS-13 (a disintegrin-like metalloprotease with thrombospondin type I repeats 13) is a plasma protease that cleaves vWF into smaller multimers, reducing its hemostatic potency.⁹ Mutations in the ADAMTS-13 gene¹⁰ and autoantibodies against ADAMTS-13¹¹ have been shown to cause familial and acquired thrombotic thrombocytopenic purpura, respectively. In mice, ADAMTS-13 has powerful natural antithrombotic activity, and recombinant ADAMTS-13 has proved useful in preventing ischemic brain injury in experimental stroke.¹² It has been suggested that ADAMTS-13 might act as a link between thrombosis and inflammation. In inflammatory models, ADAMTS-13

has played an important role in preventing vWF-induced secretion of Weibel-Palade bodies by endothelial cells and, consequently, reducing the adhesion and extravasation of leukocytes.¹³ Other interactions that contribute to initial platelet adhesion are mediated by collagen receptors GPIa-IIa (integrin $\alpha 2\beta 1$) and GPVI, which bind to collagen in the subendothelial matrix.¹⁴ The most abundant platelet surface receptor, GPIIb-IIIa (integrin $\alpha IIb\beta 3$), is activated by adhesion to collagen or vWF or by soluble agonists, such as thrombin. After activation, GPIIb-IIIa binds fibrinogen, leading to platelet aggregation.⁴ Deficiency of this GP results in Glanzmann's thrombasthenia, a disorder characterized by petechial bleeding and the absence of platelet aggregation and clot retraction.¹⁵

The cytoplasm of platelets is rich in actin and myosin, which provide platelets the ability to change shape and to retract clots. Platelet cytoplasm consists of mitochondria, lysosomes, glycogen stores, and three types of granules that contain numerous biologically active molecules (Table 17-1). These granules are classified according to their ultrastructure, density, and contents as alpha granules, lysosomes, and dense granules. Although most of the contents of these granules are made in megakaryocytes, some are taken up from the plasma by megakaryocytes and platelets.

Alpha granules contain numerous proteins and growth factors, such as platelet-derived growth factor (PDGF), TGF- β , platelet factor-4 (also referred to as CXCL4), and vWF, which are synthesized in the megakaryocyte.¹⁶ Other proteins, such as fibrinogen, enter the alpha granules from the plasma via GPIIb-IIIa receptor-mediated endocytosis.¹⁷ P-selectin (CD62P), an adhesion molecule, also is localized in the membrane of alpha granules¹⁸ and redistributes to the cell surface during platelet activation. Platelet P-selectin has been implicated in stabilizing platelet aggregates.¹⁹ The best documented high-affinity counterreceptor for P-selectin is P-selectin glycoprotein ligand-1 (PSGL-1), a transmembrane sialomucin found on leukocytes and lymphoid cells,²⁰ through whose interaction platelets participate in the inflammatory response.²¹

Dense granules contain serotonin, adenosine diphosphate (ADP), adenosine triphosphate, and calcium. The dense granule membrane bodies are made in megakaryocytes, but they do not acquire their content of serotonin and calcium until platelets are released into the circulation.²² Another series of intracellular membrane vesicles serves as a reserve to increase membrane surface area on platelet activation.

As stated previously, platelets are small cytoplasmic fragments derived from megakaryocytes. Although megakaryocytes are rare in the bone marrow (approximately 0.1% of all nucleated cells), they are easily recognized by their giant size (50 to 100 μ m diameter) and large, multilobed nucleus. Megakaryocytes have two unique characteristics: (1) They undergo a process known as *endomitosis*, in which the nucleus accumulates many times the normal number of chromosomes, and (2) they have specialized structures in the cytoplasm that permit fragments to be shed, as platelets, into the bloodstream.²³

With a life span of just about 10 days, every day, about 2×10^{11} platelets are released into the bloodstream of healthy adults by mature megakaryocytes. This quantity can be increased 10-fold under specific conditions. In humans, as in other species, there is an inverse relationship between platelet count and mean platelet volume.²⁴ This suggests that platelet production by bone marrow megakaryocytes is regulated to maintain a constant total platelet mass. The tendency toward a stable platelet mass explains the wide variation in platelet count in healthy donors (150,000/ μ L to 450,000/ μ L). Megakaryocytes normally replace about 10% of the platelet mass daily. In response to the increased need for platelets, megakaryocytes modify their number, size, and ploidy. Changes in free levels of thrombopoietin, the main physiologic regulator of platelet production, are responsible for these morphologic and functional adaptations in megakaryocytes.

Thrombopoietin is an 80- to 90-kD GP produced mainly by the liver and released at a constant rate into the circulation. Thrombopoietin acts through its receptor, also known as c-Mpl, which is present in platelets, megakaryocytes, and, to a lesser extent, most other hematopoietic precursor cells. Thrombopoietin prevents apoptosis of megakaryocytes, while increasing their number, size, and maturation,²⁵ but it does not seem to increase the rate of shedding of platelets into the circulation.²⁶ On circulating platelets, thrombopoietin is not a sufficiently strong stimulus to trigger platelet function, but it reduces the threshold for activation by other agonists, such as ADP.²⁷ Binding to the platelet thrombopoietin receptor is the major route of catabolism, however, of circulating thrombopoietin. When the platelet production rate decreases, the platelet mass and the quantity of thrombopoietin receptor decrease; consequently, thrombopoietin concentrations increase and megakaryocyte growth is stimulated. In conditions of high platelet mass (e.g., hypertransfusion of platelets), the number of

Table 17-1 Platelet Granule Compounds and Granule Membrane Components with a Role in the Hemostatic/Inflammatory Response

Platelet Granules	Actions	Contents
Dense granule	Proaggregating factors	Serotonin, histamine, ADP, ATP, Ca^{2+} , Mg^{2+}
Alpha granule	Adhesive glycoproteins	P-selectin, CD31, GPIIb-IIIa, fibronectin, vitronectin, thrombospondin
	Growth factors	TGF- β , PDGF, EGF, VEGF
	Platelet aggregation and chemotaxis	β -Thromboglobulin, PF4 (CXCL4), CC and CXC chemokines
	Hemostasis factors	Fibrinogen, vWF
Lysosome	Tissue destruction	Hydrolases, collagenase, cathepsins D and E

ADP, adenosine diphosphate; ATP, adenosine triphosphate; EGF, epidermal growth factor; GPIIb-IIIa, glycoprotein IIb-IIIa; PDGF, platelet-derived growth factor; PF4, platelet factor-4; TGF, transforming growth factor; VEGF, vascular endothelial growth factor; vWF, von Willebrand factor.

Modified from Rendu F, Brohard-Bohn B: The platelet release reaction: granules' constituents, secretion and functions, *Platelets* 12:261, 2001.

thrombopoietin receptors increases, thrombopoietin concentrations decrease, and megakaryocyte growth decreases. In addition to thrombopoietin, other soluble factors, such as interleukin (IL)-3, IL-6, IL-11, stem cell factor, or granulocyte-macrophage colony-stimulating factor, seem to promote megakaryocyte growth and maturation. Some of these soluble proteins may play a relevant role in thrombocytosis conditions.²⁸

Under normal conditions, the spleen stores about one-third of circulating platelets. Circumstances that increase splenic volume, such as hepatic cirrhosis or portal hypertension, cause a reduction in the circulating platelet count by a sequestration within the splenic sinusoids. Hypersplenism does not reduce platelet life span, however; rather, it reduces the circulating platelets available for effective hemostasis. After senescence, platelets are removed from the circulation by the reticuloendothelial system. Only a small fraction of circulating platelets is consumed in forming hemostatic plugs to maintain vascular integrity.

FUNCTION OF PLATELETS

In response to vascular injury, platelets adhere to subendothelium, secreting a variety of potent agonists and aggregating to form a hemostatic plug. During the inflammatory response, these physiologic responses of platelets can promote and exacerbate inflammation. In this sense, platelets are authentic inflammatory cells.

HEMOSTASIS

When a blood vessel is injured, a complex process involving biochemical reactions and cell-cell and cell-matrix interactions, termed *hemostasis*, occurs. The initial hemostatic response is mediated by platelets that form the platelet plug (Figure 17-1).

Figure 17-1 Platelet plug formation. Platelet activation can be initiated by several mechanical (vessel wall injury, disruption of atherosclerotic plaques) or chemical (adenosine diphosphate, epinephrine, thromboxane A₂, and thrombin) stimuli. In response to vessel wall injury, platelets attach to subendothelial matrix (adhesion); this is followed by fibrinogen-mediated platelet-platelet interaction (aggregation). Simultaneously, platelets release their intracellular granule contents (secretion), leading to recruitment of additional circulating platelets (amplification).

Figure 17-2 Anatomy of a platelet plug. Electron micrograph of a group of platelets (P) attached to an endothelial cell (EC)²⁰ in the initial platelet plug formation. Several dense granules (d) and alpha granules (α) are visible. The central platelet shows long dendritic extensions or filopodia (F). (Courtesy Dr. Lucio Díaz-Flores.)

Under physiologic conditions, the undamaged endothelium prevents the adherence of platelets by several mechanisms. These mechanisms include a cell-associated ecto-ADPase (CD39) and the production of nitric oxide and prostacyclin.²⁹ When blood vessel integrity is disrupted, the first reaction is vasoconstriction, which reduces blood loss. Simultaneously, subendothelial matrix elements are exposed, and platelets are rapidly transformed into sticky cellular elements capable of adhering to the underlying surface. Platelet adhesion is initially mediated by the interaction of the GPIb-IX-V receptor complex with vWF in the subendothelial matrix.⁵ This interaction transduces signals through the GPIb-IX-V complex that activate platelet integrins.³⁰ The activation of GPIa-IIa and GPIIb-IIIa integrins allows the binding to collagen (GPIa-IIa) and vWF (GPIIb-IIIa), mediating the stable adhesion of platelets to the subendothelial surface. In addition to vWF, the active form of GPIIb-IIIa binds fibrinogen.³¹ The association of soluble fibrinogen with GPIIb-IIIa creates bridges between platelets that result in platelet aggregation and thrombus growth. In concert with aggregation, platelets release their intracellular granules, amplifying the hemostatic response (see Table 17-1).^{32,33} The outcome is the formation of a platelet plug and triggering of the coagulation cascade, which leads to thrombin generation and resulting fibrin clot formation (Figure 17-2).

One response of platelets to activation by stimuli such as shear stress or collagen is the release of vesicles called *platelet microparticles*, fragments 0.1 to 0.2 μm in diameter that carry antigens present in intact platelets. These platelet-derived microparticles may play a role in normal hemostasis.^{34,35} The number of clinical disorders associated with elevated platelet microparticles is increasing,^{36,37} including several rheumatic diseases in which the number of circulating platelet microparticles seems to be associated with disease activity.^{38,41} The relevance of platelet-derived microparticles in the pathophysiology of those disorders needs to be fully clarified; however, it has been demonstrated that platelets intensify the inflammatory response in joint⁴² (Figure 17-3).

Figure 17-3 Platelets can be involved in the development of arthritis. The passive K/BxN model of arthritis is induced by administration of arthritogenic serum containing antibodies to glucose-6-phosphate isomerase (GPI). The graph shows arthritis severity after K/BxN serum transfer in mice administered a platelet-depleting antibody (red squares) or isotype control (blue squares). Data show the mean \pm standard error of the mean (SEM).⁴² Arrows indicate parenteral administration of platelet-depleting antibody; arrowhead, K/BxN serum administration. These findings suggest that platelets are required for arthritis development in vivo in this model.

GLYCOPROTEIN IIB-IIIa

GPIIb-IIIa is a member of a family of cell-adhesion receptors termed *integrins*. It also is referred to as integrin α IIB β 3 or CD41/CD61. Although integrins are expressed on virtually all nucleated cells, GPIIb-IIIa is restricted to megakaryocytes and platelets. It is the most abundant receptor on the platelet surface, averaging 80,000 copies per platelet. GPIIb-IIIa recognizes at least five different adhesive ligands⁴³: fibronectin, fibrinogen, vWF, thrombospondin, and vitronectin. Cells can modify integrin functions through dynamic modulation of receptor affinity.⁴³ On resting platelets, GPIIb-IIIa does not bind soluble fibrinogen. After platelet stimulation (e.g., by thrombin, collagen, or ADP), GPIIb-IIIa undergoes a conformational change, however, and is converted from a low-affinity to a high-affinity fibrinogen receptor, a process

known as *inside-out signaling*. In this situation, fibrinogen bridges the activated platelets, and platelet aggregation occurs. Simultaneously, the cytosolic portion of the activated GPIIb-IIIa binds to platelet cytoskeleton proteins and mediates platelet spreading and clot retraction in what is referred to as *outside-in integrin signaling*. GPIIb-IIIa integrates receptor-ligand interactions on the external face of the membrane with cytosolic events in a bidirectional fashion.⁴ This is the final common pathway for platelet aggregation, regardless of the mode of platelet stimulation. The importance of GPIIb-IIIa integrin is illustrated by Glanzmann’s thrombasthenia, a bleeding disorder caused by mutations in the gene for the α IIB- or the β 3-subunit,¹⁵ and by the clinical utility of GPIIb-IIIa antagonists as antithrombotic agents in the treatment of thrombotic diseases. Glycoprotein IIB-IIIa inhibitors are now recommended by international guidelines in patients with acute coronary syndromes undergoing percutaneous coronary intervention.

ROLE OF PLATELETS IN THE INFLAMMATORY RESPONSE

The accumulation of leukocytes in tissue is an essential event for the inflammatory response. The current paradigm of leukocyte extravasation requires a multistep cascade of sequential leukocyte–endothelial cell interactions, in which members of three different families of adhesion receptors participate: selectins, integrins, and the immunoglobulin superfamily.⁴⁴ Platelets contribute in many ways to leukocyte accumulation in the inflammatory foci (Table 17-2).

In flowing blood, leukocytes roll on adherent activated platelets, mainly through the interaction of platelet P-selectin with its major leukocyte ligand, PSGL-1.⁴⁵ This initial rolling of leukocytes on platelet P-selectin is followed by their firm adhesion and subsequent migration—processes that depend on the leukocyte integrin Mac-1 (α M β 2, CD11b/CD18).^{45,46} Mac-1 adheres firmly to platelets through direct binding to glycoprotein Ib α (GPIb α , CD42b).⁴⁷ These interactions provide molecular mechanisms for leukocyte recruitment to hemostatic plugs where platelets have been previously deposited in response to vascular injury.⁴⁸ Parallel lines of investigation have shown that resting platelets are able to roll on activated endothelial cells, apparently through an interaction between PSGL-1 expressed in platelets and the endothelial P-selectin.⁴⁹ The

Table 17-2 Platelet Components Implicated in the Inflammatory Response

	Platelet Component	Actions
Surface molecules	P-selectin (CD62P), PECAM (CD31), GPIb α PAF, ROS CD154 (CD40 ligand)	Adhesive targets for leukocytes Neutrophil activation Agonist for endothelial cells
Soluble factors	Serotonin, histamine β -Thromboglobulin, PF4 Acid hydrolases, ROS PDGF, TGF- β	Regulators of vascular permeability Chemotaxis Tissue destruction Cellular mitogens, chemoattractant
End products of platelet procoagulant activity	Thrombin, fibrin	Promote leukocyte accumulation

GPI, glycosyl phosphatidylinositol; PAF, platelet-activating factor; PDGF, platelet-derived growth factor; PECAM, platelet–endothelial cell adhesion molecule; PF4, platelet factor-4; ROS, reactive oxygen species; TGF, transforming growth factor.

physiologic function of platelet rolling on stimulated endothelial cells needs to be clarified. If this contact results in activation of platelets, however, those platelets may release proinflammatory mediators, such as cytokines, chemokines,^{50,51} and eicosanoid precursors,⁵² or growth factors that stimulate tissue healing. Activated platelets in circulation stimulate secretion of Weibel-Palade bodies from endothelial cells *in vivo*; this leads to P-selectin-mediated leukocyte rolling.⁵³ Given the important role of platelet P-selectin in chronic inflammatory processes,^{54,55} this effect of activated platelets might represent an important pathway of platelet-induced inflammation.

In addition to the adhesion molecules, activated platelets express on their surface two major proinflammatory mediators: platelet-activating factor (PAF) and CD40 ligand (CD154). PAF is a potent platelet-aggregating phospholipid produced by macrophages, mast cells, platelets, endothelial cells, neutrophils, and monocytes. Upon cell activation, PAF is rapidly synthesized and translocated to the plasma membrane of endothelial cells, where it recognizes its receptor in neutrophils, resulting in β_2 integrin-mediated adhesion of leukocytes to the endothelial surface.⁵⁶ In the same way, PAF can signal neutrophils when it is displayed on the surface of adherent activated platelets acting in cooperation with P-selectin to tether neutrophils.⁵⁶ The biologic action of PAF is physiologically inactivated by plasma and cellular acetylhydrolase.⁵⁷ A role of PAF in the pathogenesis of chronic inflammatory arthritis has been proposed⁵⁸; however, a well-controlled clinical trial failed to show any beneficial effect of a PAF antagonist in patients with active rheumatoid arthritis (RA).⁵⁹

CD40 is a transmembrane protein member of the tumor necrosis factor (TNF) receptor family. CD40 is present on many cells, including B cells, monocytes, macrophages, dendritic cells, and vascular endothelial cells. Platelets are the major peripheral blood source of CD154, the ligand of CD40, and they express it on their surface within seconds of exposure to an agonist. The interaction of CD154 on activated platelets with CD40 on endothelial cells causes a proinflammatory reaction of the endothelium characterized by expression of inflammatory adhesion molecules, such as E-selectin, vascular cell adhesion molecule-1 (CD106), and intercellular adhesion molecule-1 (CD54), and secretion of the chemokines IL-8 (CXCL8) and monocyte chemoattractant protein-1 (CCL2).⁶⁰ CD154 expressed on activated platelets can provide a potent stimulus to the inflammatory response. Clinical data from an open-label study suggested that the blockade of CD154 with a biologic may induce a prothrombotic state in patients with lupus nephritis through a mechanism not clarified.⁶¹ A phase II, double-blind, placebo-controlled study evaluating the safety and efficacy of a humanized monoclonal antibody against CD154 in patients with active systemic lupus erythematosus failed to show clinical efficacy. In this study, the type and frequency of adverse events were similar between the intervention and placebo groups.⁶²

When platelets adhere, they release numerous growth factors, such as PDGF, TGF- β , and other factors that are chemotactic for monocytes, macrophages, and fibroblasts. These growth factors may play an important role in the chronic inflammatory response by mediating a

fibroproliferative response. PDGF is a homodimer or heterodimer molecule of A and B chains⁶³ produced by platelets, monocytes or macrophages, endothelial cells, and vascular smooth muscle cells (under some conditions). This molecule plays an essential role in tissue repair and wound healing.⁶⁴ PDGF is a potent mitogen and chemoattractant for smooth muscle cells, connective tissue cells, and macrophages⁶⁵⁻⁶⁸; it contributes to the formation of lesions of atherosclerosis,^{68,69} a disorder strongly related to the inflammatory response.⁷⁰ It has been shown that PDGF is a potent mitogen for synovial fibroblasts isolated from patients with RA.⁷¹

TGF- β has three isoforms (TGF- β 1, TGF- β 2, and TGF- β 3) secreted by virtually all cell types as latent complexes that need to be processed to exhibit biologic activity.⁷² Several effects have been associated with TGF- β : (1) It is chemotactic for various cell types, including leukocytes; (2) it inhibits proliferation of most cells; (3) it induces the synthesis and deposition of extracellular matrix; and (4) it stimulates the formation of granulation tissue.⁷³ The net result is that TGF- β is mainly an inhibitor of the inflammatory response.⁷⁴ Carefully regulated expression of active TGF- β is essential for resolution of inflammation and repair. Systemic administration of TGF- β 1 has antagonized the development of polyarthritis in susceptible rats.⁷⁵ Overproduction of this cytokine has been associated with several fibrotic processes.^{76,77} TGF- β is a major cytokine involved in the pathogenesis of fibrosis in systemic sclerosis.⁷⁸ Blockade of cell surface molecules capable of activating latent TGF- β and blockade of ligand by antibody, soluble TGF- β receptors, and a recombinant latency-associated peptide, as well as inhibitors for ALK5 and Smad3, are potential strategies for abolishing the pathologic activation of TGF- β in systemic sclerosis.

Several reactive oxygen species are released from unstimulated platelets and after platelet stimulation with agonists such as collagen or thrombin.^{79,80} Because reactive oxygen species have been implicated in direct tissue injury and in inflammatory reactions through promotion of adhesive interactions between inflammatory and endothelial cells,⁸¹ reactive oxygen species originating from platelets may act as an autocrine or paracrine mediator that participates in the amplification of the inflammatory response in disorders such as rheumatic diseases.

PLATELETS AND RHEUMATIC DISEASES

Alterations in Platelet Numbers in Rheumatic Diseases

Increases in platelet counts have three major causes: (1) reactive or secondary thrombocytosis; (2) familial thrombocytosis; and (3) clonal thrombocytosis, including essential thrombocythemia and related myeloproliferative disorders. The platelet count is frequently elevated in patients with active RA and juvenile chronic arthritis, owing to reactive thrombocytosis. The level of thrombocytosis correlates with clinical and laboratory parameters of disease activity. Relapses of RA are often accompanied by increases in platelet count, whereas remissions are associated with their reduction, to normal limits.⁸² This activity indicates that

the thrombocytosis observed in patients with rheumatic disease is reactive or occurs secondary to the chronic inflammatory process. Although the mechanism responsible for thrombocytosis is uncertain, increased intravascular coagulation with a compensatory increase in platelet production has been suggested as a possible cause.⁸³ More recently, several studies suggested that inflammatory cytokines with a minor role in the physiologic production of platelets, such as IL-6, IL-1, or TNF, among others,^{84,85} may be active mediators in the regulation of thrombopoiesis during the reactive thrombocytosis that occurs in the inflammatory process.

Reduced platelet count, or thrombocytopenia, is common in rheumatic diseases. The mechanisms involved in thrombocytopenic states include reduction in platelet production, sequestration, and rapid platelet destruction. Several drugs used in rheumatic diseases are able to suppress the bone marrow. Among drugs that can produce thrombocytopenia because of megakaryocytic hypoplasia are gold, cyclophosphamide, methotrexate, penicillamine, and azathioprine. The effect these compounds have on suppressing megakaryocyte replication depends on the time and dose of exposure; reduced elimination of these drugs places patients at increased risk for this complication.⁸⁶

The normal spleen contains about 30% of the platelet mass, and splenomegaly can result in a low circulating count without reduction in the platelet life span.⁸⁷ Several rheumatic diseases may lead to this type of thrombocytopenia. The best known is Felty's syndrome, an uncommon but severe subset of seropositive RA complicated by granulocytopenia and splenomegaly. In this disorder, thrombocytopenia usually is not life threatening.

Another related disease is immune-mediated platelet destruction,⁸⁸ a disorder termed *idiopathic thrombocytopenic purpura*. Autoantibodies cause idiopathic thrombocytopenic purpura, and platelet surface proteins, including GPIIb-IIIa, GPIb-IX, GPIa-IIa, GPV, and GPVI, can be antigenic targets of such autoantibodies.^{89,90} Circulating platelets coated with immunoglobulin (Ig)G autoantibodies undergo accelerated clearance through Fcγ receptors expressed by macrophages in the spleen and liver. In some cases of idiopathic thrombocytopenic purpura, platelet production seems to be reduced, either by intramedullary destruction of antibody-coated platelets or by inhibition of megakaryocytopoiesis.⁹¹ The level of thrombopoietin is not increased,⁹² suggesting a normal megakaryocyte mass. Idiopathic thrombocytopenic purpura is present in 15% to 25% of patients with systemic lupus erythematosus⁹³ and in about 25% of patients with antiphospholipid syndrome.⁹⁴

In contrast, the thrombocytopenia that occurs during episodes of systemic vasculitis has a more complex pathogenesis, a worse clinical course, and a poorer outcome.^{95,96} Immune thrombocytopenia is rare in RA except when related to therapy. Among the drugs that can produce thrombocytopenia in RA, intramuscular gold salts are the most clearly associated with drug-induced immune thrombocytopenia. About 1% to 3% of patients receiving intramuscular gold salts for the treatment of RA develop a thrombocytopenia, which may be life-threatening. Although, as stated previously, bone marrow suppression can occur in patients undergoing gold treatment, thrombocytopenia is usually due to immune destruction of platelets associated with an active marrow.⁹⁷

Role of Platelets in the Pathogenesis of Rheumatic Diseases

The role that platelets play in amplification of the inflammatory response provides a basis for their involvement in rheumatic diseases. Most of the available evidence implicating platelets in the pathogenesis of rheumatic disorders is indirect and circumstantial; however, current findings based on pharmacologic and genetic experimental procedures demonstrate a previously unappreciated role for platelet microparticles in the pathogenesis of rheumatic diseases.⁴²

Platelets have been implicated in the pathogenesis of RA^{2,98} on the basis of several studies that have documented the presence of platelet proteins in the synovial fluid of RA patients⁹⁹ and on the observation that labeled platelets localize only to joints with clinically active inflammation.¹⁰⁰ Levels of plasma-soluble P-selectin are increased in RA patients compared with controls,¹⁰¹ indicating platelet activation in this disease. A direct correlation has been observed between platelet-derived microparticle levels and disease activity in RA patients; this suggests that generation of platelet microparticles^{38,41} contributes to the pathogenesis of RA. Microparticles are abundant in RA, psoriatic arthritis, and juvenile idiopathic arthritis synovial fluid both in suspension and adhered to the surface of leukocytes. Solid evidence supports that platelet microparticles are generated by platelet activation via the collagen receptor GPVI, locally in the synovial tissue. Once in the joint, microparticles seem to play a proinflammatory role, exerting potent IL-1-mediated activation of resident synoviocytes⁴² (Figure 17-4). These findings support platelet GPVI as a potential target for arthritis treatment.

Several studies have focused on the presence of activated platelets in patients with systemic lupus erythematosus.¹⁰²⁻¹⁰⁴ The risk for thrombosis is increased significantly in these patients, and platelets have been implicated in the prothrombotic state of systemic lupus erythematosus through the release of microparticles⁴⁰ and by the increased deposition of complement activation product C4d on the platelet surface.^{105,106} Patients with essential thrombocythemia have an increased prevalence of antiphospholipid antibodies, which may be associated with a higher risk of thrombosis.¹⁰⁷ The presence of activated platelets and enhanced aggregation of platelets have been described in patients with antiphospholipid syndrome,¹⁰³ systemic sclerosis,^{108,109} primary Raynaud's phenomenon¹⁰⁸ and ankylosing spondylitis.¹¹⁰

INHIBITION OF PLATELET FUNCTION BY PHARMACOLOGIC AGENTS

Nonsteroidal anti-inflammatory drugs (NSAIDs) serve as the foundation of therapy in many rheumatic diseases. NSAIDs inhibit prostaglandin synthesis¹¹¹ through blockade of cyclooxygenase (COX). These agents can interfere with platelet aggregation and secretion^{112,113} through the inactivation of platelet COX-1. In platelets, this enzyme is a rate-limiting step in the transformation of arachidonic acid into thromboxane A₂, a potent platelet-aggregating agent. In addition, some NSAIDs reduce platelet

Figure 17-4 Model of how platelet microparticle (MP) generation might contribute to joint inflammation.⁴² Circulating platelets make contact with extracellular matrix collagen type IV of fenestrated subsynovial capillaries. This contact generates platelet MPs, which once in the synovial membrane activate resident synoviocytes through potent interleukin (IL)-1 activity.

aggregation by interfering with the activation of GPIIb-IIIa through a COX-independent mechanism.¹¹⁴ NSAIDs inhibit platelet function and can lead to bleeding complications in patients with rheumatic diseases.

Newly developed potent antithrombotic agents also might provide new weapons in the treatment of rheumatic diseases. Among these are ticlopidine and its analogue, clopidogrel—two inhibitors of the P2Y₁₂ ADP receptor. Nowadays, many other members of this family of antiplatelet agents are being tested for control of procoagulant states.¹¹⁵ These agents have greater efficacy than aspirin for the prevention of recurrent stroke¹¹⁶ and may find a place in the antirheumatic armamentarium as a result of their potential anti-inflammatory properties.^{117,118} However, no information is available about clinical trials specifically designed to test the effect of P2Y₁₂ inhibitors in the control of rheumatic diseases. Agents that interfere directly with the adhesive function of integrin GPIIb-IIIa have come into therapeutic use. This new group of agents includes monoclonal antibodies (abciximab), cyclic peptides (eptifibatide), and other small molecules that have been approved for intravenous coronary angioplasty and stent procedures. Orally active GPIIb-IIIa blockers have been developed for long-term therapy, including secondary and even primary prevention of thrombotic diseases. However, available data from clinical trials of these oral agents have failed to show clinical benefit, whereas they have shown unexplained increased mortality.¹¹⁹

Innate Immunity

STEVEN A. PORCELLI

KEY POINTS

Innate immunity depends on recognition of conserved molecular patterns found in many microorganisms.

Several families of pattern recognition receptors are responsible for triggering innate immune responses.

Toll-like receptors and other pattern recognition receptors with leucine-rich repeat domains play a key role in innate immune recognition.

Antimicrobial peptides are important effectors of innate immunity.

Phagocytic cells and several types of innate-like lymphocytes are key cell types in mediating innate immunity.

Innate immune responses have a strong impact on the development of adaptive immunity.

Some defects in the innate immune system are associated with a predisposition to infection or to autoimmune disease.

It has become common practice in immunology to divide the mechanisms involved in host defense into adaptive and innate components; this provides a useful framework for classifying the numerous cells, receptors, and effector molecules that combine to make up the vertebrate immune system (Table 18-1). A specific immune response, such as the production of antibodies or T cells against a particular pathogen, is referred to as *adaptive immunity* because it represents an adaptation that occurs during the lifetime of an individual as a result of exposure to that pathogen. Adaptive immune responses involve the clonal expansion of T and B lymphocytes bearing a large repertoire of somatically generated receptors that can be selected to recognize virtually any pathogen. The adaptive immune system of any given individual is profoundly molded by the immunologic challenges encountered by that individual during the course of a lifetime. A hallmark of adaptive immune responses is that they are highly specific for the triggering agent, and they provide the basis for immunologic memory. This property of memory endows the adaptive immune response with its “anticipatory” property, which provides increased resistance against

future infection with the same pathogen and also allows vaccination against future infectious threats.

Adaptive immunity is essential for the survival of all mammals and most other vertebrates, but a wide variety of other mechanisms that do not involve antigen-specific lymphocyte responses are also involved in successful immune protection. These diverse mechanisms are collectively known as *innate immunity* because they are not dependent on prior exposure to specific pathogens for their amplification. Such responses are controlled by the products of germline genes that are inherited and similarly expressed by all normal individuals. Innate immune mechanisms involve both constitutive and inducible components and use a wide variety of recognition and effector mechanisms. It has become clear in recent years that innate immune responses have a profound influence on the generation and outcome of adaptive immune responses. This ability of the innate immune system to instruct the responses of the adaptive immune system suggests many ways in which innate immunity can influence the development of both long-term specific immunity and autoimmune disease.

EVOLUTIONARY ORIGINS OF INNATE IMMUNITY

In spite of its obvious importance for most vertebrate organisms, the adaptive immune system is a relatively recent evolutionary development (Figure 18-1). In the great majority of present-day vertebrate species, the adaptive immune system is based on the ability to generate large families of variable lymphocyte receptors with immunoglobulin-like structures. This ability has been conserved owing to the acquisition of a specialized recombination system that mediates the assembly of gene segments in the T cell and B cell receptor families, which most likely occurred through invasion of the genome of a primitive vertebrate by a transposable element or virus carrying this machinery.¹ This critical step in the evolution of the immune system can be traced back to the emergence of the ancestors of present-day jawed fish, which represent the most primitive extant species known to have adaptive immune systems based on the generation of large families of specific immunoglobulin-type receptors.² Recently, other systems of variable lymphocyte

Table 18-1 Contrasting Features of Innate and Adaptive Immune Systems

Property	Innate Immune System	Adaptive Immune System
Receptors	Relatively few (several hundred?) Fixed in genome Gene rearrangement not required	Many (potentially 10^{14} or more) Encoded in gene segments Gene rearrangement required
Distribution	Nonclonal All cells of a class identical	Clonal All cells of a class distinct
Targets	Conserved molecular patterns Lipopolysaccharides Lipoteichoic acids Glycans and peptidoglycans Others	Details of molecular structure Proteins Peptides Carbohydrates
Self–non–self-discrimination	Perfect: selected over evolutionary time	Imperfect: selected in individual somatic cells
Action time	Immediate or rapid (seconds to hours)	Delayed (days to weeks)
Response	Microbicidal effector molecules Antimicrobial peptides Superoxide Nitric oxide Cytokines (IL-1, IL-6, others) Chemokines (IL-8, others)	Clonal expansion or anergy of specific T and B lymphocytes Cytokines (IL-2, IL-4, IFN- γ , others) Specific antibody production Specific cytolytic T cell generation

IFN, interferon; IL, interleukin.

Modified from Medzhitov R, Janeway CA Jr: Innate immune recognition, *Annu Rev Immunol* 20:197, 2002.

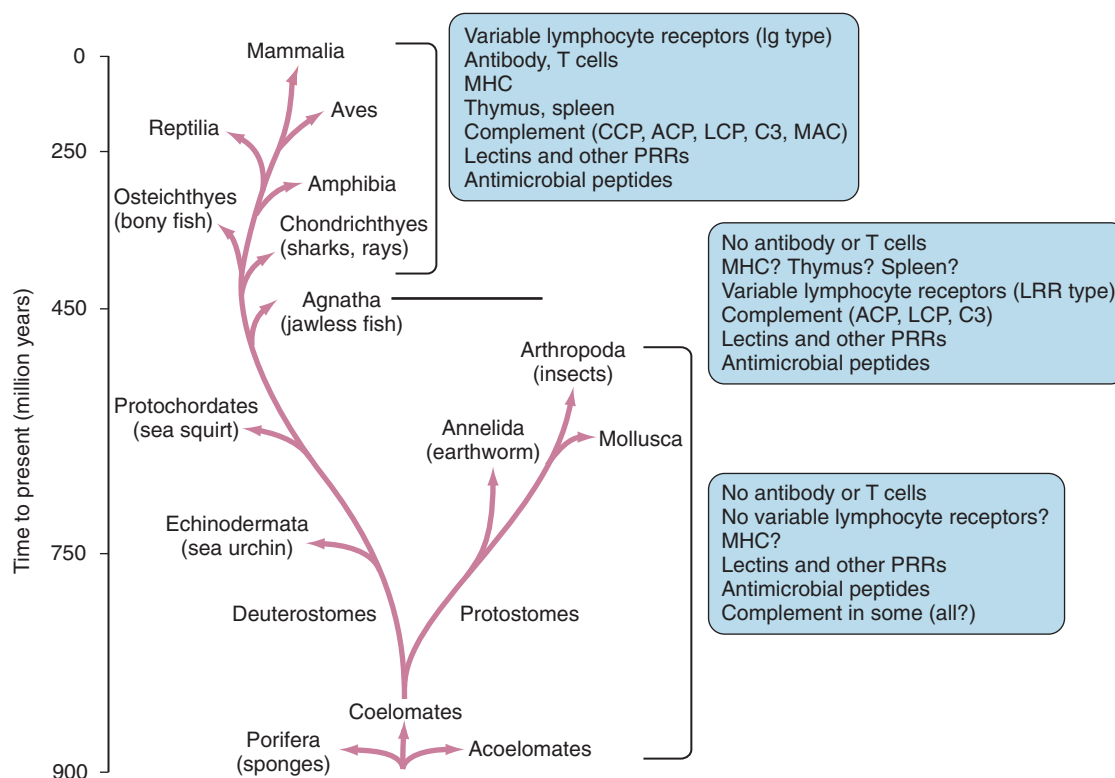

Figure 18-1 Ancient evolutionary origin of the innate immune system. Studies of the immune systems of a wide range of vertebrates and invertebrates have revealed that even the most primitive invertebrates possess many components of innate immunity (e.g., pattern recognition receptors of the lectin and Toll-like families, antimicrobial peptides, complement proteins). The innate immune system is thus extremely ancient, having arisen early in the evolution of multicellular life. In contrast, the adaptive immune system is a much more recent development that did not appear until emergence of the ancestors of present-day sharks and rays, approximately 400 million years ago. The first species to acquire an adaptive immune system based on immunoglobulin-type receptors must have arisen after the appearance of the direct ancestors of present-day jawless fish (lampreys and hagfish), which are the most highly evolved living species that lack the ability to generate large families of variable immunoglobulin-type lymphocyte receptors (arrow). ACP, alternative complement pathway; CCP, classic complement pathway; Ig, immunoglobulin; LCP, lectin-activated complement pathway; LRR, leucine-rich repeat domain; MAC, membrane attack complex; MHC, major histocompatibility complex; PRR, pattern recognition receptor. (Adapted from Sunyer JO, Zarkadis IK, Lambris JD: Complement diversity: a mechanism for generating immune diversity? *Immunol Today* 19:519, 1998.)

receptors that are unrelated to immunoglobulins but also provide the basis for an adaptive immune response have been discovered in primitive jawless fish such as lampreys and hagfish.³ This finding shows that at least two different strategies for the creation of an adaptive immune system emerged at the dawn of vertebrate evolution about 500 million years ago, and it emphasizes the importance of adaptive immunity for survival and further evolution of the vertebrate lineages.

Given this key role of adaptive immunity in the evolution and survival of vertebrates, it is surprising that all invertebrate animals, and possibly some of the lowest vertebrate species as well, completely lack the ability to generate lymphocyte populations bearing large families of clonally diverse antigen receptors.^{4,5} In these animals, protection against pathogen invasion depends entirely on innate immunity, elements of which appear to exist in all animals and plants and must have evolved with the earliest multicellular forms of life. In many cases, components of the innate immune system are significantly conserved in structure and function in animals from the lowliest invertebrates to the most complex vertebrates.⁴ This preservation of innate immune mechanisms, with their functions largely intact, over such vast evolutionary distances is a clear indication of their importance, even in animals that have developed sophisticated adaptive immune responses.

PATHOGEN RECOGNITION BY THE INNATE IMMUNE SYSTEM

Some mechanisms of innate immunity are constitutive, meaning that they are continuously expressed and are not significantly modulated by the presence or absence of infection. Examples include the barrier functions provided by epithelial surfaces continuously exposed to microbial flora, such as those of the skin and intestinal and genital tracts. In contrast, the inducible mechanisms of innate immunity involve increased production of mediators and upregulation of effector functions that eliminate microorganisms. Induction occurs as a result of exposure to a wide variety of microbes and represents a less specific form of immune recognition than that associated with the specific antibodies and T cells that mediate adaptive immunity. The basic principle underlying this form of response is a process known as *pattern recognition*. This recognition strategy is based on the detection of commonly occurring and conserved molecular patterns that are essential products or structural components of microbes.

PAMPS AND DAMPS: PATTERNS FOR INNATE IMMUNE RECOGNITION

Pathogen-Associated Molecular Patterns

The general name given to the targets of innate immune recognition in microbes is *pathogen-associated molecular patterns* (PAMPs). These structural features or components distinctive for microorganisms are not normally found in the animal host. The best-known example of a PAMP is bacterial lipopolysaccharide (LPS), a ubiquitous glycolipid constituent of the outer membranes of gram-negative bacteria. Another important example is the peptidoglycan

structure present as the basic cell wall component in nearly all bacteria. These structures may vary partially from one bacterium to another, but the basic elements are conserved, thus providing the possibility of recognizing a broad array of pathogens by sensing a single or a relatively small number of PAMPs. Many PAMPs that serve as targets of recognition for the innate immune response are now known to be associated with bacteria, fungi, and viruses.

In addition to allowing direct recognition of molecules produced by various microorganisms, the innate immune system is able to respond to the patterns of host-derived molecules released by cells undergoing necrotic death. The molecules recognized are generally referred to as *damage-associated molecular patterns* (DAMPs), and include multiple different families of proteins, as well as nonproteinaceous substances such as uric acid microcrystals.^{6,7} Thus, the response to DAMPs can be an indirect response to microbial invasion, or it can be triggered by other types of tissue damage such as ischemia to result in sterile inflammation.

Pattern Recognition Receptors

Recognition of PAMPs and DAMPs is mediated by a collection of germline-encoded molecules known collectively as *pattern recognition receptors* (PRRs) (Table 18-2). These receptors are host proteins that have evolved, through many millions of years of natural selection, to possess precisely defined specificities for particular PAMPs or DAMPs expressed by microorganisms. The total number of PRRs present in complex vertebrates such as humans is estimated to be several hundred—a number limited by the size of the genome of any animal and the number of genes it can dedicate to immune protection. The human genome, for example, is estimated to contain approximately 20,000 to 35,000 genes, most of which are not related directly to the immune system. This demonstrates one of the strong points of contrast between innate and adaptive immune systems, because the latter can possess in the range of 10^{14} different somatically generated receptors for foreign antigens in the form of antibodies and T cell receptors. With its much more limited array of receptors, the innate immune system uses the strategy of targeting highly conserved PAMPs that are shared broadly by large classes of microorganisms. Because most pathogens contain PAMPs, this strategy allows the generation of at least partial immunity against most infections.

PRRs are expressed by many cell types, some of which are specialized effector cells of the immune system (e.g., neutrophils, macrophages, dendritic cells, lymphocytes), and others of which are not generally regarded as part of the immune system (e.g., epithelial and endothelial cells). Unlike the T and B cell receptors used for adaptive immune recognition, expression of PRRs is not clonal, which means that all receptors displayed by a given cell type (e.g., macrophages) have identical structure and specificity. When PRRs are engaged by recognition of their associated PAMPs or DAMPs, effector cells bearing the PRRs are triggered to perform their immune effector functions immediately, rather than after undergoing proliferation and expansion, as in the case of adaptive immune responses. This accounts for the much more rapid onset of innate immune responses.

Table 18-2 Pattern Recognition Receptors (PRRs)

Receptor Class	Examples	Prominent Sites of Expression	Major Ligands	Function
Secreted PRRs	Collectins Mannan-binding lectin Ficolins Surfactant proteins (SP-A, SP-B) Pentraxins Short pentraxins (CRP, SAP) Long pentraxins	Plasma	Carbohydrate arrays typical of bacterial capsules, fungi, and other microbes Apoptotic cells and cellular debris, including chromatin	Complement activation Opsonization
Endocytic PRRs	Lectin-family receptors Macrophage mannose receptor DEC-205 Dectin-1 Scavenger receptor A MARCO Complement receptors CD11b/CD18 (CR3) CD21/35 (CR2/1)	Macrophages, dendritic cells, some endothelia, epithelia, and smooth muscle cells	Cell wall polysaccharides (mannans and glucans), LPS, LTA, and opsonized cells and particles	Pathogen uptake by phagocytes Delivery of ligands to antigen-processing compartments Clearance of cellular and extracellular debris
Signaling PRRs	Toll-like receptors CARD/NOD proteins Pyrin domain proteins	Macrophages, dendritic cells, epithelia	Multiple conserved pathogen-associated molecular patterns (LPS, LTA, dsRNA, lipoproteins, flagellin, bacterial DNA, others)	Activation of inducible innate immunity (antimicrobial peptides, cytokines, reactive oxygen or nitrogen intermediates) Instruction of adaptive immune response

CARD, caspase activation and recruitment domain; CR, complement receptor; CRP, C-reactive protein; DEC-205, dendritic and epithelial cells, 205 kD; dsRNA, double-stranded RNA; LPS, lipopolysaccharide; LTA, lipoteichoic acid; MARCO, macrophage receptor with collagenous structure; NOD, nucleotide-binding oligomerization domain; SAP, serum amyloid P protein; SP, surfactant protein.

In recent years, considerable progress has been made toward identifying many of the important PRRs involved in the induction of innate immunity. These receptors can be classified into three functional classes: secreted, endocytic, and signaling PRRs (see Table 18-2). In addition, many of the known PRRs can be classified into structurally defined families on the basis of a few characteristic protein domains. Among these, the best known include proteins with calcium-dependent lectin domains, scavenger receptor domains, and leucine-rich repeat domains.

Pattern Recognition Receptors of the Lectin Family

Calcium-dependent lectin domains are common modules of secreted and membrane-bound proteins involved in the binding of carbohydrate structures. A well-characterized PRR belonging to this class is the *mannan-binding lectin* (MBL), also known as *soluble mannose-binding protein*, which represents a secreted PRR that functions in initiation of the complement cascade (Figure 18-2).^{8,9} This protein is synthesized primarily in the liver on a constitutive basis, although its production can be increased as an acute phase reactant following many types of infection. MBL binds to carbohydrates on the outer membranes and capsules of many bacteria, as well as fungi, some viruses, and parasites. Although mannose and fucose sugars bound by MBL can also be found on the surfaces of normal mammalian cells, they are present at too low a density or in the wrong orientation to efficiently engage the lectin domains of MBL. In contrast, the coats of many microorganisms contain an array of these sugars, which allows strong binding of MBL. Thus, in this case, the spacing and orientation of specific carbohydrate residues constitute the PAMP that triggers the

activation of innate immunity by MBL. MBL functions as one of a small number of secreted PRRs that can initiate the lectin pathway of complement activation. At least two other soluble proteins with lectin activity in human plasma, known as *ficolins* (ficolin/P35 and H-ficolin), can also activate this pathway following their interaction with bacterial polysaccharides.¹⁰

Several of the soluble lectin-type PRRs also play an important role in the opsonization of microbes by binding to their surfaces and directing them to receptors on phagocytic cells. Among these are two pulmonary surfactant proteins, SP-A and SP-D, which similarly recognize and bind to the surface sugar codes of microbes in the respiratory tract.¹¹ These molecules are similar in structure to MBL, having both collagen-like and lectin domains, and together they constitute a family of soluble PRRs known as *collectins*. Another family of soluble PRRs that performs a similar function in plasma is the pentraxins, so called because they are formed by the association of five identical protein subunits.¹² This family includes the acute phase reactants C-reactive protein (CRP) and serum amyloid P protein (SAP), along with a number of so-called long pentraxins, which have an extended polypeptide structure with homology to the classic short pentraxins (i.e., CRP and SAP) only at their carboxy-terminal domains. Long pentraxins are expressed in a variety of different tissues and cells, and their specific functions are mostly unknown. However, the long pentraxin PTX3 has been shown to play an important, nonredundant role in resistance to fungal infection in mice, and recent studies indicate that PTX3 is essentially a functional ancestor of antibodies that recognizes microbes and promotes their clearance through complement activation and phagocytosis.¹³

Figure 18-2 Structure and function of mannan-binding lectin (MBL), a soluble pattern recognition receptor. *Left*, MBL is a multimer protein structure with multiple carbohydrate-binding lectin domains. Three identical 32-kD polypeptides associate to form a subunit, which then oligomerizes to form functional complexes (the trimeric form consisting of three subunits is illustrated, which is one of several different oligomer sizes that has been observed for MBL). Each polypeptide in the subunit contains an N-terminal cysteine-rich domain, a collagen-like domain, a neck region, and a C-terminal carbohydrate recognition domain. *Right*, Initiation of the lectin pathway for complement activation by MBL. The carbohydrate recognition domains of MBL bind to carbohydrates that are characteristic of bacterial surfaces. This leads to the recruitment of several other serum proteins, including small MBL-associated protein (sMAP) and the three MBL-associated serine proteases (MASP1, MASP2, MASP3). The protease activity of MASP2 cleaves complement C4 and C2 subunits, generating the C3 convertase (C4bC2a). MASP1 is able to cleave C3 directly. The deposition of C3 cleavage products on the bacterial surface results in opsonization and phagocytosis of the bacterial cell.

In addition to these soluble proteins, a large number of membrane-bound glycoproteins with lectin domains are known to exist; some of them participate in innate immunity by serving as endocytic PRRs for the uptake of microbes or microbial products^{14,15} (Figure 18-3). One of the most extensively studied of these is the macrophage mannose receptor (MMR).¹⁶ Although originally identified on alveolar macrophages and known to be expressed on macrophage subsets throughout the body, this receptor is also expressed on a variety of other cell types, including certain endothelia, epithelia, and smooth muscle cells. The MMR is a membrane-anchored, multilectin domain-containing protein that mediates the binding of a broad range of pathogens, leading to their internalization via endocytosis and phagocytosis. Although the major function of the MMR appears to be directing the uptake of its ligands, evidence suggests that this receptor may be capable of signaling to modify macrophage functions following receptor engagement.¹⁷ Another member of this receptor family, the β -glucan binding cell-surface lectin known as *dectin-1*, has a role in the modulation of inflammation in a mouse model of infection-induced arthritis.¹⁸

Pattern Recognition Receptors of the Scavenger Receptor Family

The scavenger receptor family contains a broad range of structurally diverse cell surface proteins that are expressed most prominently on macrophages, dendritic cells, and endothelial cells¹⁹ (see Figure 18-3). Although they were originally defined by their ability to bind and take up modified serum lipoproteins, they also bind a wide range of other ligands, including bacteria and some of their associated products. Multiple members of this family have been

implicated as PRRs for innate immunity. These include the scavenger receptor A (SR-A) and a related molecule called the *macrophage receptor with collagenous structure* (MARCO).²⁰ Both of these molecules contain a scavenger receptor cysteine-rich domain in the distal ends of their membranes and a collagen-like stalk with a triple-helical structure. Both are known to bind bacteria, and SR-A also binds well-known PAMPs such as lipoteichoic acids and LPS.^{21,22} Mice that have been made deficient in SR-A by targeted gene disruption show increased susceptibility to infections caused by a variety of bacteria, thus providing strong evidence of the role of scavenger receptors in protective immunity, most likely through the activation of innate immune mechanisms.^{23,24} Members of the class B scavenger receptor family, including CD36 and SR-BI/CLA-1, have also been found to recognize a variety of pathogen-derived molecules.¹⁹ Although these members of the scavenger receptor family clearly function as endocytic PRRs in the uptake of microbes, their potential to serve as signaling receptors has not yet been established. However, several scavenger receptors play a co-receptor role in the signal transduction process mediated by members of the Toll-like receptor (TLR) family (discussed later), most likely by capturing specific ligands and transferring them to adjacent TLRs.¹⁹

Pattern Recognition Receptors with Leucine-Rich Repeat Domains

Leucine-rich repeat domains (LRRs) are structural modules found in many proteins, including PRRs involved in signaling the activation of innate immunity. Molecules in this class include, most notably, the family of mammalian Toll-like receptors (TLRs), which are membrane-bound signal-transducing molecules that play a central role in the

Figure 18-3 Endocytic pattern recognition receptors of the scavenger receptor and lectin families. *Left*, Illustrations of three members of the scavenger receptor family. These are trimeric complexes of type II transmembrane polypeptides that have their N-terminals positioned in the cytoplasm and their C-terminals in the extracellular space. Three distinct extracellular structural domains are indicated: (a) the scavenger receptor cysteine-rich (SRCR) domain (absent in SR-A II), which has no currently known function; (b) the collagen-like domain, which is implicated in the binding of polyanionic ligands; and (c) the α -helical coiled-coil domain (absent in macrophage receptor with collagenous structure [MARCO]), which is believed to assist in receptor trimerization. *Right*, Two examples of multilectin domain endocytic pattern recognition receptors—macrophage mannose receptor (MMR) and DEC-205. Distinct extracellular domains in these receptors include (d) a cysteine-rich N-terminal domain, (e) a fibronectin-like domain, and (f) multiple calcium-dependent (C-type) lectin domains that bind various carbohydrate ligands. (Reproduced in part from Peiser L, Mukhopadhyay S, Gordon S: Scavenger receptors in innate immunity, *Curr Opin Immunol* 14:123, 2002.)

recognition of extracellular and vacuolar pathogens.²⁵ Two families of cytoplasmic LRR-containing receptors have also been identified; they play a prominent role in the innate immune recognition of PAMPs expressed by intracellular pathogens. These include the families of caspase activation and recruitment domain (CARD) proteins and of pyrin domain proteins.²⁶ Molecules are closely related in structure and function to proteins found in invertebrates and plants involved in pathogen resistance, highlighting the ancient origin of these pathways for host defense; they appear to have been recognizably conserved throughout approximately 1 billion years of evolution.

Toll-like Receptors. The first member of the Toll family to be discovered was the *Drosophila* Toll protein, which was identified as a component of a signaling pathway that controls dorsoventral polarity during development of the fly embryo.²⁷ The sequence of Toll showed it to be a transmembrane protein with a large extracellular domain containing multiple tandemly repeated LRRs at the N-terminal end, followed by a cysteine-rich domain and an intracellular signaling domain (Figure 18-4). A role for Toll in immune responses was suggested by the observation that its intracellular domain shows homology to the mammalian interleukin-1 receptor (IL-1R) cytoplasmic domain.²⁸ This association was later confirmed in studies showing that Toll

was critical for the antifungal response in the fly, linking this pathway for the first time to innate immunity.²⁹ Identification of *Drosophila* Toll eventually led to a search for similar proteins in mammals; this effort has been richly rewarded, yielding a family of 10 Toll-like receptors (TLRs) in humans and 12 in mice.³⁰ Among these, TLR1 through TLR9 are conserved between mice and humans, TLR10 is present only in humans, and TLR11 through TLR13 are expressed only in mice.³⁰ All these molecules contain large extracellular domains with multiple LRRs, as well as intracellular signaling domains known as Toll/IL-1R, or TIR, domains.³¹ Many of these TLRs have been linked to innate immune responses against various PAMPs of different microorganisms.³²

Toll-like Receptor 4 and the Response to Lipopolysaccharide. The first human TLR to be identified was the molecule now designated TLR4, which is a major component in the response to one of the most common of all PAMPs—bacterial LPS.³³ Earlier studies on the response to LPS had identified two proteins—CD14 and LPS-binding protein—as molecules involved in the binding of LPS to the surface of LPS-responsive cells. However, these molecules did not possess any potential for transducing signals into the cell, so it was unclear how LPS binding would lead to the activation of cellular responses associated with gram-negative bacterial infection. The answer was provided by positional cloning studies of the LPS gene in the LPS-hyporesponsive C3H/HeJ mouse.³⁴ This study revealed a single amino acid substitution in the signaling domain of TLR4. Specific deletion of the *TLR4* gene by targeted gene disruption in mice subsequently confirmed the essential role of this molecule in the response to LPS, because TLR4 knockout mice have almost no response to LPS and are highly resistant to endotoxic shock.^{35,36} Biochemical studies provide further support for TLR4 as a component of the LPS receptor; they show that LPS bound to the surface of cells is in close contact with both CD14 and TLR4, as well as another protein called MD-2, which appears to perform an accessory function in the binding of LPS to the receptor complex.³⁷ Additional studies have elucidated many of the downstream elements in the signaling pathways that connect TLR4 to the activation of genes associated with inducible innate immunity³⁸ (see Figure 18-4). Studies of Toll signaling pathways in *Drosophila* have identified the transcription factor nuclear factor κ B (NF κ B) as one of the key effectors of gene activation following the engagement of Toll. This basic pathway in the fly appears to be largely conserved in TLR signaling in higher animals, including mammals.³⁹

Other Pathogen-Associated Molecular Patterns Recognized by Toll-like Receptors. The search for ligands that lead to signaling through various TLRs has demonstrated that this family of PRRs is collectively responsible for innate immune responses to an extraordinary array of PAMPs. In addition to its central role in the signaling of responses to LPS, TLR4 is involved in responses to multiple different self- and non-self-ligands.³⁰ The antimetabolic agent and cancer chemotherapy drug paclitaxel (Taxol) has been shown to mimic LPS-induced signaling in mouse cells through a pathway that requires both TLR4 and MD-2.⁴⁰ Other foreign ligands of TLR4 include the fusion protein (F protein) of respiratory syncytial virus⁴¹ and the heat shock

Figure 18-4 Toll-like receptors (TLRs) and associated proteins. *Left*, TLR4 is a transmembrane polypeptide present in the plasma membrane as a homodimer. The TLR4 polypeptide has three distinct extracellular regions: (a) an N-terminal flanking domain; (b) the leucine-rich repeat (LRR) region, which contains 21 leucine-rich motifs and is thought to be directly involved in binding to lipopolysaccharide (LPS) and other ligands; and (c) a C-terminal flanking cysteine-rich domain. The cytoplasmic domains of TLR4 and all other TLRs have homology to the human interleukin (IL)-1 receptor and are designated Toll-IL-1 receptor (TIR) domains. The extracellular portion of TLR4 associates with at least two other proteins, CD14 and MD-2, which are involved in ligand recognition. The intracellular TIR domains associate with multiple adapter proteins (MyD88, TIRAP/MAL, Tollip), which link the receptor complex to kinases that activate signaling cascades. For TLR4, and probably for most other TLRs as well, activation of the IL-1 receptor-associated kinase (IRAK) is an important step leading to release of the active form of transcription factor nuclear factor κ B (NF κ B). In addition, signaling through TLR4 leads to signal transduction through the activation of mitogen-activated protein kinases (MAPKs), double-stranded RNA-binding protein kinase (PKR), and other members of the IRAK family such as IRAK-2. *Right*, A different set of ligands is recognized by TLR2, which functions as part of a heterodimeric complex with other TLRs such as TLR6. The TLR2-TLR6 complex shares many features with the TLR4 complex in terms of its associated proteins. However, the TIR domain of TLR2 also appears to recruit phosphatidylinositol-3-OH kinase (PI3 kinase, p85 and p110 subunits) and the membrane-associated GTPase Rac1, which allows the activation of other signaling molecules such as the serine-threonine kinase Akt. Thus, although the major signaling pathways activated by different TLRs are similar or identical (i.e., activation of NF κ B and MAPKs), it is likely that each TLR complex has subtle differences in its secondary pathways of signal transduction. These differences may lead to partially overlapping but distinct outcomes in response to ligands recognized by different TLR complexes. (Adapted from Underhill DM, Ozinsky A: *Toll-like receptors: key mediators of microbe detection*, *Curr Opin Immunol* 14:103, 2002.)

protein 60 (HSP60) of chlamydia.⁴² TLR4 can signal in response to mammalian HSP60, a protein expressed at increased levels and most likely released by stressed or damaged cells.⁴³ This represents a variation of the pattern recognition principle in which the pattern is an endogenous molecule released by damaged host cells that serves as a DAMP, rather than a PAMP produced directly by a pathogen. Other examples of recognition of DAMPs by TLR4 include responses to oligosaccharide breakdown products of tissue hyaluronans and responses to the extra-domain A region of fibronectin produced by alternative RNA splicing in response to tissue injury or inflammation.^{31,44}

The range of PAMPs recognized through TLR2 is probably even greater than for TLR4. TLR2 is known to be involved in signaling in response to multiple PAMPs of gram-negative and gram-positive bacteria, including such structures as bacterial glycolipids, bacterial lipoproteins, parasite-derived glycolipids, and fungal cell wall polysaccharides.³⁰ TLR2 does not function independently in responding to these PAMPs; rather, it forms heterodimers with TLR1 or TLR6. This ability to pair with other TLRs appears to be unique to TLR2, because other TLRs that have been studied carefully (e.g., TLR4, TLR5) most likely function only as monomers or homodimers. Other TLRs with currently defined ligands are TLR5 (involved in the response to bacterial flagellin), TLR3 (double-stranded RNA), TLR7 (single-stranded RNA), and TLR9 (unmethylated bacterial DNA).³⁰ It is apparent that most, if not all,

microbes contain multiple PAMPs that are recognized by different TLRs. For example, a typical bacterium expressing LPS also contains unmethylated DNA and thus generates signals not only through TLR4 but potentially through TLR9 as well. Because different TLRs are capable of activating distinct signaling cascades (see Figure 18-4), the ability of a single cell to detect several different features of a pathogen simultaneously with multiple TLRs may help the innate immune response to be more finely tuned to respond to a particular challenge.⁴⁵

CARD and Pyrin Domain Proteins. A large number of cytosolic proteins that have structural similarities to membrane-bound TLRs and that function as sensors for PAMPs of intracellular pathogens and regulators of innate immune responses have been identified. Many of these proteins contain LRR domains and have been classified on the basis of their incorporation of a CARD or pyrin domain. The nomenclature and classification schemes for this growing family of innate immune sensors and regulators are still evolving, and it has been proposed that they should be grouped and classified as members of a single family designated the CATERPILLER (CARD, R [purine]-binding, pyrin, lots of leucine repeats) family.⁴⁶ However, the most recent literature shows a trend toward referring to this group of proteins as the *NLR family*, an acronym that stands for either “nucleotide-binding domain, leucine-rich repeat proteins”⁴⁷ or “Nod-like receptors.”³⁰ The first intracellular microbial sensors in this family to be described were the

Nod1 and Nod2 proteins, which contain LRR domains linked to a central nucleotide binding and oligomerization (NOD or NACHT) domain and an N-terminal CARD domain.⁴⁸ As in the case of TLRs, the LRR domains of these proteins appear to be involved in the recognition of pathogen-derived molecules and a variety of host components that function as DAMPs, and their CARD domains are linked to downstream signaling for the activation of innate immunity. Although originally implicated in response to bacterial LPS, it is now well accepted that both Nod1 and Nod2 are primarily involved in the recognition of murpeptide monomers released from bacterial cell wall peptidoglycans.²⁶ Signals resulting from the recognition of peptidoglycan components by Nod1 and Nod2 lead to activation of the NF κ B pathway, as in the case of TLR signaling. However, other signaling pathways also appear to be engaged, such as activation of procaspase-1 and caspase-9 by CARD domain interactions, leading to increased production of IL-1 β and cell death through a process referred to as *pyroptosis*.⁴⁷

The pyrin domain-containing proteins represent a major subgroup of NLRs that are believed to signal in response to microbial invasion or cellular stress. The prototype member of this family is pyrin, which is the product of the gene that is mutated in those with familial Mediterranean fever.⁴⁶ Although pyrin itself lacks an LRR domain, numerous other members of this family contain an LRR linked to a central NOD domain and an N-terminal pyrin domain. These include cryopyrin (also known as NLRP3 or NALP3), which is mutated in patients with a range of hereditary inflammatory diseases referred to collectively as *cryopyrin-associated periodic syndromes*.⁴⁷ Cryopyrin, together with these multiple related proteins, constitutes a large set of related proteins known as the NLRP (NLR-PYRIN domain) or Nalp (NACHT-LRR-PYRIN domain-containing proteins) family.²⁶ The human genome contains 14 genes encoding NLRP proteins, the precise functions of which are still largely unknown.³⁰ However, several NLRP proteins, particularly NLRP3 and NLRP1, have been identified as key components in the formation of intracellular complexes known as *inflammasomes*. These cytosolic protein complexes serve as activating platforms that are involved in the activation of caspases—intracellular proteases required for the processing of inflammatory cytokines such as IL-1 β and IL-18.^{47,49} Direct recognition of specific PAMPs by NLRP proteins remains to be established, although initial studies implicate these proteins as direct or indirect sensors of various stimuli, including constituents of bacteria (peptidoglycan, bacterial RNA, exotoxins), viruses (double-stranded RNA), and uric acid crystals.^{30,47,50-53}

EFFECTOR MECHANISMS OF INNATE IMMUNE RESPONSES

The ability to recognize pathogens through PRRs allows activation of numerous antimicrobial effector mechanisms by the innate immune response. These responses lead to the killing of pathogens through production of effector molecules with direct microbicidal activities, including the membrane attack complex of complement, a variety of antimicrobial peptides, and the caustic reactive oxygen and reactive nitrogen intermediates generated within

phagocytic cells. In invertebrates, these mechanisms represent virtually the entire protective response against microbial invaders. However, in most vertebrates, including mammals, innate immune recognition also has profound effects on triggering and programming the adaptive immune response that follows somewhat later. This ability of the innate immune system to instruct the adaptive response has major implications for the development of long-term protective immunity to infection and may play a critical role in mechanisms leading to autoimmunity.

CELL TYPES MEDIATING INNATE IMMUNITY

Many types of cells have the ability to mount at least a limited response to PAMPs, but the most effective cell types in this regard are the specialized phagocytes, such as macrophages, neutrophils, and dendritic cells. Upon recognition of microbial stimuli, these cells have the ability to upregulate nicotinamide adenine dinucleotide phosphate (NADPH) oxidase by assembling the components of this enzyme complex on phagosomal membranes, leading to an oxidative burst that produces microbicidal superoxide ions.⁵⁴ Many phagocytic cells also increase their expression of inducible nitric oxide synthase (iNOS, or NOS2) upon contact with various PAMPs.⁵⁵ This leads to the production of reactive nitrogen intermediates, including nitric oxide and peroxynitrite, which have potent direct antimicrobial activities. These responses are synergistic because the antimicrobial activity of the phagocyte oxidase system is frequently enhanced by the expression of reactive nitrogen intermediates.

Innate-like Lymphocytes

A number of distinct lymphocyte subsets also play important roles in innate immune responses. One group of such lymphocytes, the natural killer (NK) cells, appears to be a true member of the innate immune system. These lymphocytes do not express receptors generated by somatic recombination and thus depend on germline-encoded receptors for signaling their responses against pathogen-infected cells.⁵⁶ NK cells participate in the early innate response against virally, and probably bacterially, infected cells through expression of cytotoxic activity and secretion of cytokines.⁵⁷

Several other subsets of lymphocytes belonging to the T and B cell lineages have been identified as participants in the rapid response against pathogens to which the host has not previously been exposed. Although these cells express clonally variable, somatically rearranged antigen receptors (T cell antigen receptors or membrane immunoglobulins) and thus could be classified as components of the adaptive immune system, their manner of functioning is much more characteristic of innate than adaptive immunity. These innate-like lymphocytes (ILLs) may represent remnants of the earliest primitive adaptive immune system, and they appear to have been conserved to varying degrees because they continue to make specialized contributions to host immunity.⁵⁸

Among the currently recognized ILLs are two B cell populations, known as the B1 and marginal zone B cell

subsets.^{59,60} These are involved in the spontaneous production of natural antibodies, which are largely germline-encoded immunoglobulins that are reactive to commonly expressed microbial determinants. In addition, both of these B cell populations generate rapid T cell-independent responses following bacterial challenges and thus contribute to the first line of immune defense that precedes the onset of adaptive immunity.

Among the T cells, two populations of ILLs have been identified and characterized in detail: $\gamma\delta$ T cells and NK T cells. The $\gamma\delta$ T cells express somatically rearranging receptors that use a limited number of variable region genes and are thought to recognize a narrow spectrum of foreign or self-ligands.⁶¹ In humans, the specificities of two subsets of $\gamma\delta$ T cells have been at least partially defined. One of these, the major circulating population expressing the V δ 2 gene product, responds rapidly and without prior immunization to a variety of small alkyl phosphate and alkyl amine compounds that are produced by many bacteria. Another subset, characterized by its expression of the V δ 1 gene product, responds to major histocompatibility complex (MHC) class I-related self-molecules of the MHC class I chain-related A and B (MICA/B) and CD1 families.⁶¹ These molecules may serve as markers of cellular stress and are upregulated on cells in the context of infection or inflammation, leading to the activation of V δ 1-bearing $\gamma\delta$ T cells.

A similar principle appears to be involved in the functioning of NK T cells, which are so named because of their co-expression of an $\alpha\beta$ T cell antigen receptor and a variety of receptor molecules that are typically associated with NK cells.⁶² Similar to $\gamma\delta$ T cells, NK T cells have somatically rearranged antigen receptors that use a limited array of V genes and most likely recognize a narrow range of foreign or self-antigens. A major population of NK T cells is reactive with the MHC class I-like CD1d molecule, and these ILLs appear to be activated by recognition of a variety of lipid or glycolipid ligands that can be presented by CD1d. Recently, several bacterial glycolipids have been identified as specific antigens that stimulate NK T cells, suggesting that these cells may be rapid responders that contribute to innate antibacterial immunity.⁶³ A wide variety of mouse disease models have shown that NK T cells also make significant contributions to the development of adaptive immune responses and may play a particularly important role in immunoregulation to prevent autoimmunity.^{62,63}

Antimicrobial Peptides

Antimicrobial peptides are the key effector molecules of inducible innate immunity in many invertebrates and are being increasingly recognized as important elements of innate immunity in higher animal species, including mammals.⁶⁴ They are evolutionarily ancient components of host defense that are widely distributed throughout all multicellular organisms in the animal and plant kingdoms. More than 1,000 such peptides have been identified, and their diversity is so great that it is difficult to categorize them. However, at a structural and mechanistic level, most of these peptides share several basic features. They generally are composed of amino acids arranged to create an amphipathic structure with hydrophobic and cationic regions. The

cationic regions target a fundamental difference in membrane design between microbes and multicellular animals, which is the abundance of negatively charged phospholipid head groups on the outer leaflet of the lipid bilayer. The preferential association of antimicrobial peptides with microbial membranes leads to membrane-disrupting activity, most likely involving the interaction of the hydrophobic regions of the peptide with membrane lipids.⁶⁵

Antimicrobial peptides produced in response to engagement of various PRRs account for most of the inducible immunity against microbes noted in many invertebrate animals and plants. Although these peptides are probably less central to host immunity in most vertebrates, evidence indicates that they make important contributions to immunity in more highly evolved animals, including mammals.⁶⁶ In humans, active antimicrobial peptides, such as the α - and β -defensins, are constitutively or inducibly produced in skin and epithelia of the gastrointestinal and respiratory tracts.⁶⁷ These molecules most likely act as natural preservatives of epithelia that are colonized or frequently exposed to microbial flora. Because the acquisition of resistance against these agents by sensitive microbial strains is extremely unusual, antimicrobial peptides are of great interest as templates for the development of new antimicrobial pharmaceuticals.^{67,68}

INFLUENCE OF INNATE MECHANISMS ON ADAPTIVE IMMUNITY

In addition to functioning as a first line of defense against invading pathogens, a critical feature of the innate immune system in higher animals such as mammals is its effect on activating the adaptive immune system. In fact, it is now clear that in most situations, the adaptive immune system mounts a response to a pathogen only after the pathogen has generated signals via PRRs of the innate immune system. This principle serves as the basis for the adjuvant effect, which is the observation that antibody and T cell responses are efficiently generated against protein antigens only if these are introduced together with a nonspecific activator of the immune system, which is generically known as an *adjuvant*. Most adjuvants are in fact extracts or products of bacteria, and it is clear that in most or all cases, adjuvant effects result from activation of the innate immune response.⁶⁹

Innate immune responses can prime or potentiate the adaptive immune response in many ways (Figure 18-5). In the case of T cell responses, one extremely important and well-recognized mechanism involves the upregulation of co-stimulatory molecules. T cells require at least two signals to become activated from a naïve resting state. One signal is provided through the T cell antigen receptor by its binding to a specific peptide ligand presented by an MHC class I or II molecule. The second signal is provided by one of several co-stimulatory ligands that are expressed by specialized antigen-presenting cells such as dendritic cells (see Chapter 13). The best studied of these are the molecules of the B7 family—B7-1 (CD80) and B7-2 (CD86)—which engage the activating receptor CD28 on the surface of the T cell. Expression of B7 family co-stimulatory molecules on the surface of antigen-presenting cells is controlled by the innate immune system, such that these molecules are

Figure 18-5 Instruction on the adaptive immune response by the innate immune system. When an antigen-presenting cell (APC) comes into contact with pathogen-bearing pathogen-associated molecular patterns (PAMPs), responses are triggered via innate immune mechanisms that dramatically alter the ability of the APC to stimulate an adaptive (T cell-mediated) immune response. For example, signals generated by contact with PAMPs such as lipopolysaccharide (LPS) with Toll-like receptor 4 (TLR4) lead to the activation of transcription factor nuclear factor κ B (NF κ B), which enters the nucleus of the APC and assists in switching on genes for cytokines (e.g., interleukin [IL]-1, -6, and -12 and a variety of chemokines) and co-stimulatory molecules (e.g., the B7 family members CD80 and CD86). In addition, binding of the pathogen to endocytic pattern recognition receptors (PRRs) such as the mannose receptor leads to delivery of the pathogen to endosomes (Endo) and lysosomes (Lys). There, the protein antigens of the pathogen are partially degraded to generate antigenic peptides that can be presented by major histocompatibility complex (MHC) class II molecules for recognition by the T cell antigen receptors (TCRs) of specific T cells. These effects of pattern recognition by the innate immune system lead to expression of the signals required for activation of quiescent antigen-specific T cells and the subsequent generation of specific antibodies. (Adapted from Medzhitov R, Janeway C Jr: *Innate immunity*, N Engl J Med 343:338, 2000.)

induced to appear at functional levels only after PRRs, such as members of the TLR family, have been activated by recognition of their cognate PAMPs or DAMPs.³³

Recent studies have shown that innate immune signaling through TLRs has a major impact on the responses of phagocytic antigen-presenting cells; it also provides an important second signal for immunoglobulin production by B cells. In the case of phagocytic cells, uptake of microbes by phagocytosis and subsequent maturation of the phagosome are stimulated by concurrent TLR signaling.⁷⁰ In dendritic cells, which are the major antigen-presenting cells for the priming of T cell responses, TLR signaling has a major impact on whether antigens from phagocytosed microbes are effectively presented on MHC class II molecules.⁷¹ For B cells responding to foreign antigens, it has been demonstrated that concurrent signaling through TLRs is necessary for the efficient stimulation of T cell-dependent differentiation into plasma cells and subsequent antibody secretion.⁷² This concept is also relevant for T cell responses to autoantigens, including several prominent nuclear antigens that are targets of autoantibodies in rheumatic disease.^{73,75}

Innate immune responses also trigger the production of many cytokines and chemokines, which enhance the development of adaptive immune responses and change the

nature of the adaptive response generated. For example, contact between dendritic cells and PAMPs such as LPS or bacterial lipoproteins leads to the production of IL-12 as a result of signaling through TLRs.^{69,76} This cytokine acts on antigen-specific T cells to promote their differentiation into T helper type 1 cells, which are associated with the production of interferon- γ and other effector mechanisms that favor the clearance of bacterial pathogens.⁷⁷ In the case of myeloid lineage dendritic cells, signaling through TLRs (and potentially other PRRs) induces a process known as *maturation*, which is associated with increased expression of antigen-presenting and co-stimulatory molecules that enables the efficient priming of naïve antigen-specific T cells.⁷⁸

This requirement for the innate immune response to “switch on” the expression of molecules required for the priming and differentiation of T cell responses helps ensure that proinflammatory adaptive immune responses occur mainly in the setting of a relevant infectious challenge. After activation, helper T cells control other components of adaptive immunity, such as the activation of cytotoxic T cells, B cells, and macrophages. Innate immune recognition, therefore, appears to control all major aspects of the adaptive immune response through the initial recognition of infectious microbes by PRRs. The discovery of self-molecules that act as DAMPs further extends this paradigm to include immune responses that are triggered by tissue damage. This more extended view, sometimes referred to as the “danger model,” helps explain why certain self-ligands produced or released in the setting of infection or tissue damage can function in essentially the same manner as the PAMPs associated with microorganisms.^{79,80}

DISEASE ASSOCIATIONS INVOLVING INNATE IMMUNITY

Given the obvious role of the innate immune response in virtually all types of infectious disease, one might expect that gross defects in the mechanisms of innate immunity occur relatively rarely and in association with clinical immunodeficiency. In fact, increasing evidence indicates that mutations that inactivate various innate immune pathways can lead to increased pathogen sensitivity in both laboratory mice and humans.^{8,23,66,81,82} Because many of the pathways leading to innate immunity are amplified during recurrent or prolonged activation of the immune system, they must also participate in mediating tissue damage in chronic inflammatory disease. In addition, certain self-molecules that are produced or released at increased levels as a result of inflammation, including heat shock proteins, nucleic acids, and microcrystals of monosodium urate or calcium pyrophosphate, may act as DAMPs.^{42,73,75,83,84} These may signal through TLRs or other PRRs to stimulate adjuvant-like effects that increase the potential for autoreactive lymphocytes to be activated.

Perhaps a more surprising finding has been that some defects in innate immunity are associated with a markedly increased predisposition to autoimmune disease. Several different mechanisms have been proposed to explain this paradoxical association. Mechanisms of the innate immune response play an important role in the clearance of self-antigens released from necrotic or apoptotic cells, resulting in a noninflammatory clearance of self-antigens that tends

to favor tolerance rather than the stimulation of immune responses.⁸⁵ Failure of such clearance may lead to excessive exposure to self-antigens, triggering normally silent autoreactive lymphocyte clones to expand and differentiate into effector cells. This may account for the development of lupus-like autoimmunity in mice with targeted deletion of the gene for the short pentraxin SAP, which, along with other components of the innate immune system, appears to play a significant role in the clearance of DNA-chromatin complexes.⁸⁶ Reduced levels of serum mannose-binding lectin in humans also appear to be a risk factor for the development of systemic lupus erythematosus, possibly because of the role of this soluble PRR in facilitating the clearance of apoptotic cells.⁸⁷

Deficiencies of early components of the classic pathway of complement activation have been strongly associated with lupus-like autoimmunity in both humans and mouse models.⁸⁸⁻⁹² This may be the result of alterations in the clearance of apoptotic cells or other sources of self-antigens, resulting in increased stimulation of normally silent autoreactive lymphocytes.^{93,94} An alternative, but nonexclusive, mechanism relates to involvement of the complement system, particularly the early components C1 and C4, in facilitating the induction of self-tolerance by the adaptive immune system by increasing the localization of autoantigens such as double-stranded DNA and nucleoproteins within the primary lymphoid compartment.^{88,95,96} Thus, a deficiency of C1 or C4 appears to result in failure to delete or functionally inactivate autoreactive B cell clones as they arise during lymphopoiesis in the bone marrow.^{95,97} Studies carried out in mouse models suggest that this tolerance-inducing mechanism is partially disrupted in animals that are deficient in a variety of other components of innate immunity, including SAP and the complement receptors CD21/CD35.^{86,95}

Multiple examples of links between defects in signaling receptors of the innate immune system and chronic inflammatory diseases have emerged from studies of the CARD and pyrin families of cytosolic PRRs.^{30,47} The first association of this type was provided by genetic mapping studies that identified the Nod2 protein as the product of the IBD1 locus, which contributes to disease susceptibility in a subset of patients with Crohn's disease.⁹⁸⁻¹⁰¹ This soluble PRR of the CARD family normally functions by inducing cytokine production in response to bacterial peptidoglycan, but mutant alleles associated with increased risk of Crohn's disease are defective in this function.⁹⁸ In this case, it may be failure of innate immunity to adequately control bacterial colonization or infection in the intestine that leads to the final expression of disease. Consistent with this view, a recent study has demonstrated diminished expression of a class of antimicrobial peptides (β -defensins known as *cryptdins*) in Paneth cells from the ileum of patients with Crohn's disease and *Nod2* mutations.¹⁰² Other findings suggest that defective signaling by mutant variants of *Nod2* can result in reduced production of immunoregulatory cytokines such as IL-10, perhaps resulting in uncontrolled inflammation in the intestine.¹⁰³ Other studies have established links between various members of the pyrin family and specific chronic inflammatory disorders. These include the causative association of mutations in pyrin with familial Mediterranean fever, and of cryopyrin with cryopyrin-associated periodic syndromes.^{46,47} These diseases and other chronic

inflammatory or autoimmune disorders associated with specific deficiencies in innate immune mechanisms are frequently considered together as autoinflammatory diseases.¹⁰⁴ Recognition that these diseases are frequently associated with dysregulation of inflammatory cytokine production, in particular IL-1 β , has led to some striking therapeutic advances in the treatment of selected patients using systemic administration of the IL-1 receptor antagonist anakinra.¹⁰⁵⁻¹⁰⁷

Deficiencies in at least two populations of ILLs—NK cells and NK T cells—have been associated with multiple autoimmune syndromes in both humans and mice.^{62,108-110} This is believed to reflect a significant role for these ILLs in regulating adaptive immune responses, although the precise mechanisms by which they act still are not fully understood. Given the complex interplay between innate immunity and adaptive immunity, it is extremely likely that associations between alterations in innate immunity and autoimmune diseases will continue to emerge. As for some of the examples cited here, a fuller understanding of these associations is likely to lead to new and successful therapies for autoimmune and autoinflammatory diseases.

Future Directions

The last two decades of research in immunology have seen a great emphasis on the fundamental role played by innate immune mechanisms in all immune responses. The innate immune system in humans represents the accumulation of many stages of evolution and natural selection that began with the most primitive organisms. Because of the ancient origins of the innate immune system, some of the most important discoveries in the field of innate immunity have come from studies of relatively simple animals such as flies and worms. Now that many of the pieces of this elaborate system have been discovered and categorized, continued research efforts are turning increasingly toward exploring the roles of various components of innate immunity in the human immune system. These efforts are very likely to yield insights into many currently unexplained diseases and may provide targets for new therapeutics.

Connection to the Clinic

- Innate immune responses serve as the foundation of all immunity; they participate at some level in all infectious, inflammatory, and autoimmune diseases.
- Drugs targeting specific innate immune effectors are beginning to emerge as useful therapeutic agents.
- Innate immune receptors are responsible for triggering the clinical syndromes associated with uric acid crystals and potentially other types of crystal-induced arthritis.
- Primary defects in specific innate immune molecules have been identified as the cause of a range of uncommon disorders known as *autoinflammatory diseases*.
- Many systemic autoimmune diseases are associated with genetic polymorphisms of molecules involved in innate immune responses.
- Research into innate immunity has provided important new insight into potential mechanisms for common autoimmune diseases such as Crohn's disease and systemic lupus erythematosus.

KEY POINTS

Lymphocytes are born, and many self-reactive cells are deleted in primary lymphoid tissues.

Immune responses are usually initiated in secondary lymphoid tissues.

Tertiary lymphoid tissue can be generated at sites of inflammation and may promote tissue-specific autoimmunity.

Self-tolerance is established by antigen recognition in primary lymphoid tissues or elsewhere in the absence of inflammation.

Generation of an adaptive immune response is dependent on innate immune system activation.

Dendritic cells sense both tissue-specific factors and innate immune stimuli in shaping T cell responses to antigens.

The adaptive immune system is so named because it can adapt to virtually any pathogen or toxin that enters the body. Although invertebrates defend themselves through innate immunity alone,¹ vertebrates have all developed some form of adaptive immunity—the ability to generate novel receptors by genetic recombination mechanisms that can then be selected to recognize diverse macromolecules associated with rapidly evolving pathogens.² A molecule that can be recognized by the adaptive immune system is known as an “antigen” (Table 19-1).

The ability to produce molecules and cells that can attack any biologic structure is a double-edged sword.² Although pathologic autoimmunity is not described in invertebrates, which evolved with a hard-wired immune system, it is a common problem in vertebrates.³ Self-recognition must be offset by redundant mechanisms to produce self-tolerance. We discuss some mechanisms involved in this process and the anatomy behind these in this chapter. In addition to self-antigens, animals with adaptive immunity are also exposed to many harmless environmental antigens that have the potential to induce allergic reactions.⁴ Mechanisms to distinguish self from foreign, as well as benign foreign from harmful foreign, macromolecules are critical processes in successful adaptive immunity. At the core of these mechanisms is the essential partnership of adaptive and innate immunity, first formulated by Charles Janeway, Jr.⁵ Although the adaptive immune system can recognize any foe and focus powerful effector mechanisms to destroy this foe, its ability to calculate the relative risks of mounting an immune response or becoming tolerant to a given recognized structure is guided by innate recognition

Adaptive Immunity and Organization of Lymphoid Tissues

MICHAEL L. DUSTIN

of pathogen-associated molecule patterns (PAMPs) or inflammation triggered by tissue damage–associated molecular patterns (DAMPs).

The function of the adaptive immune system is tightly linked to its anatomy.^{6,7} In some respects T lymphocytes are cells without boundaries that can be found in almost any tissue at any time. T and B lymphocytes are readily monitored in patients because they are reliably found in the blood of normal individuals. However, the vast majority of the T and B lymphocytes are located in secondary lymphoid tissues where they search for antigens. There are three types of tissues that concentrate lymphocytes—the primary lymphoid tissues, where these cells are born; the secondary lymphoid tissues, where they search for antigens; and tertiary lymphoid tissues that form at sites of chronic inflammation. Secondary and tertiary lymphoid tissues have a characteristic and functionally important organization into B cell and T cell zones. In fact, all of the previously mentioned histologic findings are directly related to functional goals of the adaptive immune system, as is clarified subsequently.

This chapter addresses the basics of adaptive immunity and its partnership with innate immunity in the context of the anatomic sites in which these responses take place.

LYMPHOCYTE MIGRATION PARADIGMS FOR HOMING, INTERSTITIAL NAVIGATION, AND EGRESS

Because we talk about adaptive immunity in the context of secondary lymphoid tissues, this is a good time to review what is known about lymphocyte migration. It has been appreciated since the early 1960s that lymphocytes “circulate” between secondary lymphoid tissues and the blood and more recently that, on activation, they take on different tissue-specific homing properties that are important for function.⁸ If one arbitrarily begins this circuit with a naïve T cell in the blood, then there are three distinct transitions that can be considered: (1) interaction with the vessel wall and extravasation; (2) interstitial locomotion in the tissue parenchyma; and (3) egress from the tissue parenchyma back into the blood, sometimes via lymph. General features of these three steps are addressed here, and relevant details will be commented on in different functional contexts in relation to adaptive immunity.

Multistep Paradigm for Extravasation

The movement of lymphocytes from blood to tissues is complicated by the high-flow rates in blood vessels. Springer

Table 19-1 Terms and Definitions

Antigen	Any molecular structure recognized by the adaptive immune system. The ligand for B cell receptor (BCR)/antibody or T cell receptor (TCR)
Chemokine	Family of small secreted or shed proteins (typically 8 kDa) that bind to G protein–coupled receptors and activate or attract cells. A chemical (<i>chemo</i> -) that induces movement (<i>-kine</i>)
Integrin	Family of adhesion molecules that are specialized for adhesion in the context of migration and generation of contractile force/mechanical stabilization. Noncovalent heterodimers that are regulated rapidly by signaling from chemokine receptors and antigen receptors
Selectin	Family of adhesion molecules that are specialized for mediating initial attachment of leukocytes to the vessel wall from flowing blood. Have amino-terminal calcium-dependent lectin domains and interact with carbohydrate ligands that can incorporate protein determinants

and Butcher⁹ established the current paradigm called the “multistep model” for T cell extravasation.

The first step is the initial tethering of the free-flowing leukocyte to the vessel wall. A special class of adhesion molecules known as selectins and their carbohydrate ligands mediates this step (see Table 19-1).¹⁰ The selectin family comprises three members: L-, E-, and P-selectin. L-selectin is expressed on naïve T and B lymphocytes and is essential for the entry of these cells into lymph nodes, but not the spleen.¹¹ The ligand for L-selectin is a complex of sulfated sialic acid bearing complex carbohydrates linked to different protein backbones expressed on high endothelial cells in postcapillary venules in primary, secondary, and tertiary lymphoid tissues.¹⁰ E- and P-selectin are expressed on activated endothelial cells at sites of inflammation in diverse tissues.¹² They bind to glycoprotein ligands expressed on leukocytes, which have terminal sialyl-Lewis-X blood group antigens and can also incorporate other structural modifications.¹³ The high affinity ligand for P-selectin is the protein backbone PSGL-1 with a stretch of sulfated tyrosines that make up part of the ligand. PSGL-1 can be expressed by lymphocytes without the necessary secondary modification to make it a ligand for P-selectin. Therefore a fusion of P-selectin to immunoglobulin Fc that can be purified and fluorescently tagged is the best probe to determine if a leukocyte is competent to bind to P-selectin expressing endothelial cells. The genetic basis of forming selectin ligands is complex with requirements for expression of core proteins, specific sialotransferases, fucosyltransferases, and sulfotransferases.¹³ Defects in fucose metabolism are the basis for a rare genetic immunodeficiency/mental retardation syndrome called *leukocyte adhesion deficiency type II* (LAD-II).¹⁴ Selectins will only mediate leukocyte tethering and rolling, not arrest and extravasation.

Selectin-mediated tethering allows the leukocyte to bring G protein–coupled receptors close enough to the vascular wall to bind ligands attached to glycoproteins.¹⁵ Chemokine receptor signaling is critical to activate closely linked integrin family members to bind their ligands.¹⁶ This chemokine signal is pertussis toxin sensitive, indicating that it involves G_i-coupled receptors. With respect to lymphocyte recirculation, there are three important chemokine receptors: CCR7, CXCR4, and CXCR5. CCR7, binding to

ligands CCL19 and CCL21, is the most important chemokine system for entry of T cells into secondary lymphoid tissues.¹⁷ CXCR4 binding to its ligand CXCL12 also contributes to entry of T and B cells.¹⁸ CXCR5, binding to its ligand CXCL13, is the major system controlling entry of B cells into secondary lymphoid tissues.¹⁹ Following activation, CCR7 is downregulated on many effector T cells and other chemokine receptors are upregulated, allowing these cells to home to peripheral sites of inflammation.²⁰ Activated endothelial cells in these tissues express ligands that selectively recruit subsets of activated T cells. In contrast, activated B cells either become memory cells that retain CXCR5 and CCR7 expression²¹ or differentiate into plasma cells that downregulate CXCR5 and CCR7 and upregulate CXCR4, targeting these cells to medullary cords via a novel migratory mechanism and bone marrow.²²

Integrin family members are the immediate recipients of chemokine signals to produce rapid arrest of rolling leukocytes and to initiate the extravasation process.¹⁶ The major integrin that mediates homing to secondary lymphoid tissues is LFA-1, which is composed of the α L and β 2 subunits. LFA-1 is expressed only on leukocytes and binds to intercellular adhesion molecules (ICAMs), of which the best characterized are ICAM-1 and ICAM-2.²³ ICAM-1 and ICAM-2 are the major ICAMs expressed on endothelial cells, with ICAM-1 displaying regulated expression in response to inflammatory mediators like tumor necrosis factor (TNF) and interferon (IFN)- γ .

The deficiency of the integrin β 2 subunit is the basis of a rare genetic syndrome known as *leukocyte adhesion deficiency type I* (LAD-I). In this disease leukocyte extravasation at sites of inflammation is defective and patients are highly susceptible to bacterial infections of the skin and mucous membranes. Patients with LAD-I are developmentally normal and can be treated by bone marrow transplantation with a high success rate.²⁴ A leukocyte adhesion deficiency type III in which multiple leukocyte integrins show defects in regulation of Rap1, a small G protein important in LFA-1 regulation, has also been described.²⁵

The structure of integrins reveals remarkable machinery for regulated adhesion.²⁶ The inactive form is folded into a compact globular structure, in which the ligand-binding domain points toward the leukocyte surface. Following activation by chemokines, the integrin extends to two times its original height and projects the ligand binding site to greater than 20 nm from the leukocyte membrane, with orientation toward the endothelial cell surface.²⁷ This dramatic change is closely coupled to cytoskeletal association, providing anchorage needed for arrest and cell spreading following ligand binding.²⁸

A second integrin expressed on naïve and activated lymphocytes called VLA-4 is composed of the α 4 and β 1 subunits and can play a small role in entry into lymph nodes but a major role in entry into inflamed sites. Its ligand is VCAM, also a member of the immunoglobulin superfamily regulated by inflammatory cytokines.²⁹ Inhibition of VLA-4 by a monoclonal antibody (natalizumab) is the basis of an approved treatment for multiple sclerosis that decreases leukocyte entry into the central nervous system.³⁰ Natalizumab therapy has been associated with rare cases of progressive multifocal leukoencephalopathy, a severe infection caused by reactivation of latent JC virus.³¹ Thus risks and benefits

need to be weighed carefully with immunosuppressive therapies even when only a single specific pathway is targeted. When T lymphocytes are activated to home to mucosal effector sites, they upregulate expression of the integrin $\beta 7$, which also associates with $\alpha 4$ to form the gut-homing integrin $\alpha 4\beta 7$, and bind a different immunoglobulin superfamily ligand called MAdCAM (for *mucosal addressin cell adhesion molecule*) expressed on endothelial cells in the gut.³²

The extravasation process involves the movement of lymphocytes between or through endothelial cells.³³ Endothelial junctional complexes include special adhesion molecules that need to be transiently disengaged to allow lymphocyte passage between endothelial cells. The transcellular pathway may be dominant in situations where the endothelial junctions are particularly sturdy, as in the brain, thymus, or lymph nodes. Both junctional and transcellular routes involved active processes in the leukocyte and endothelial cells, but this step is not thought to be regulated to control homing decisions.

To summarize, three types of receptor ligand pairs define the key regulated steps in lymphocyte homing. The compatibility of all three is required to gain entry into the tissue. If a compatible selectin-ligand pair is not available, the leukocyte will not be able to initiate adhesion to the endothelial wall and will flow past. If a chemokine receptor-chemokine pair is not available, it will be impossible to activate integrins, even if the selectin-ligand pair mediates rolling or tethering, and the cell will eventually release and remain in the blood. If the integrin-ligand pair is not compatible, the cells will not be able to arrest and extravasate, even if the selectin-ligand pair and chemokine-ligand systems are engaged. Thus, these molecular pairs can be thought of as a hierarchic area code for lymphocyte homing—the digits defined by the compatible interactions, each of which must be correctly engaged to allow entry.³⁴

Tissue Organization and Interstitial Migration

Classical histology and mouse genetics have been used to establish the molecular mechanisms that account for the segregation of T cells and B cells within secondary lymphoid tissues. The T cell zone is defined by the production of CCL19 and CCL21 by stromal cells and the expression of CCR7 on T cells.¹⁷ Interestingly, these are the same signals that trigger the arrest of T cells on endothelial cells for tissue entry. T cell zones are also amply populated by conventional dendritic cells (DCs), which express CCR7 as they mature. DCs appear to form a network on a scaffold of reticular fibers.³⁵ The parenchyma of lymph nodes and splenic white pulp nodules are crisscrossed by thick collagen bundles sheathed in fibroblastic reticular cells.³⁶ The inner compartment of these fibers forms a network of conduits in the lymph node and spleen that allows DCs in the parenchyma access to the afferent lymph or blood, respectively. The B cell follicles depend on CXCL13 expressed by follicular stromal cells and CXCR5 expressed on B cells. In fact, the balance of CXCR5 and CCR7 expression by B cells controls their proximity to the boundary between T cell zone and B cell zone, where B cells can encounter helper T cells.²¹ B cell zones are also populated by variable numbers of follicular DCs, which are differentiated stromal cells, rather than cells of hematopoietic origin.

Two-photon laser scanning fluorescence microscopy has revealed the dynamics of immune cells in secondary lymphoid tissues. Fluorescently labeled T cells moved with an average speed of 12 $\mu\text{m}/\text{min}$ in T cell zones, and B cells moved 30% slower in the follicles of acute organ-cultured lymph nodes of live mice.³⁷ The paths taken by T and B cells appeared random, but subsequent analysis of fluorescent lymphocyte movement in the presence of differentially labeled stromal cells revealed that the lymphocytes were guided by a ramified stromal network and changed direction frequently as they encountered branches in the stromal scaffolding.³⁸ The DC network is supported by the stromal network, ensuring that T cells contact DCs as they follow a random pathway through the stromal network.³⁵ Thus the process by which a DC that has brought antigen from the periphery can show this antigen to many T cells is based on forming random contacts with thousands of T cells per hour. Due to its random nature, this model has been referred to as “stochastic repertoire scanning.”

The major signal that stimulates the rapid and random migration of T and B cells in lymph nodes is thought to be chemokines presented on the surface of stromal cells. The speed of B lymphocyte migration is significantly reduced in mice lacking $G_{i\alpha 2}$ subunit of G protein-coupled receptors, further supporting the model that chemokines may have a role in this process.³⁹ Chemokines can act as chemoattractants but can also stimulate migration in a random fashion—called *chemokinesis*—under some conditions. Rapid T cell motility in vitro can be recapitulated by surfaces coated with only CCR7 ligands.⁴⁰ Somewhat surprisingly, integrins such as LFA-1 contribute little to migration of DCs or T cells.^{40,41}

Although the initial scanning process is random, once antigen-bearing DCs begin to interact with antigen-specific T cells, a number of nonrandom elements of migration are established. B cells that recognize antigen upregulate CCR7 and downregulate CXCR5 such that they are attracted to the boundary between the T and B cell zones.²¹ DCs that have been in contact with CD4^+ T cells produce CCL3 and CCL4, which attract CD8^+ T cells under inflammatory conditions.⁴² This directed migration of CD8^+ T cells biases the scanning of the CD8^+ T cell repertoire toward DCs that have received T cell help and thus have come into contact with interesting antigens. This process likely increases the efficiency of repertoire scanning.

Immunologic Synapses Maintain Antigen-Specific Interactions with Dendritic Cells

The most extreme change in lymphocyte migration during an immune response is the near full arrest referred to as an *immunologic synapse*.⁴³ In vitro analysis has revealed elaborately organized structures underlying the arrest of T cell migration in contact with DCs bearing appropriate MHC-peptide complexes.⁴⁴ In vivo imaging analysis has repeatedly revealed stable T cell–DC interactions as a common feature of both tolerance and immunity induced by high-affinity ligands.⁴⁵ Although LFA-1–ICAM-1 interactions are not necessary for migration in lymph nodes, these adhesion molecules are required for stable synapses.⁴⁶ Immunologic synapses have been proposed to lead to asymmetric cell divisions that generate effector T cell and memory T cell

precursors.⁴⁷ Dynamic T cell–DC interactions referred to as *kinapses* may set up symmetric divisions that help maintain the differentiated state of these early precursors.⁴⁸

Egress from Lymph Nodes and the Thymus: Sphingosine-1-Phosphate

The recirculation of lymphocytes requires that they periodically cease their local scanning activity or activation process in secondary lymphoid tissues and exit to the lymph or blood. This is referred to as *egress*. Egress is also important for recently matured lymphocytes to leave the bone marrow or thymus to move to secondary lymphoid tissues. Insight into the molecular processes controlling egress from lymph nodes and the thymus were provided through investigation of the fungal metabolite derivative FTY720, which has been approved as a drug (fingolimod) for treatment of relapsing-remitting multiple sclerosis.⁴⁹ FTY720 administration rapidly decreases T and B cell numbers in blood. FTY720 is phosphorylated by sphingosine kinase and acts as an agonist for a number of sphingosine-1-phosphate receptors that are expressed on lymphocytes and endothelial cells. Further insight was provided by the study of bone marrow chimeric mice in which fetal liver cells from embryonic lethal sphingosine-1-phosphate receptor 1 (S1PR1) knockout mice were used to reconstitute lethally irradiated syngeneic wild type mice.⁵⁰ The S1PR1-deficient, recently matured lymphocytes are unable to exit the thymus. Furthermore, when the mature S1PR1-deficient lymphocytes trapped in the thymus were transferred into wild-type recipients, they were able to enter lymph nodes normally but could not egress from lymph nodes due to failure to counterbalance CCR7-dependent retention signals. These results suggested a T cell autonomous defect in egress from both the thymus and lymph node. Although FTY-720-P is an agonist of S1PR1, it has the effect of downregulating expression of the receptor such that the compound recapitulates the knockout phenotype. A parallel study with a reversible S1PR1 agonists and antagonists suggests that S1PR1 also has a role in controlling lymphatic endothelium permeability and this effect would contribute to arrest of egress in a similar manner to the T cell autonomous effects.⁵¹

PRIMARY LYMPHOID TISSUES: SITES WHERE T AND B CELLS ARE GENERATED AND SELF-TOLERANCE MECHANISMS ARE INITIATED

The critical event in the birth of T and B cells is the rearrangement of the antigen receptor genes to generate T cell antigen receptors (TCRs) and B cell antigen receptors (BCRs) that are expressed on the cell surface. Each T cell and B cell has a single antigen receptor as birth certificate and identification card. The life, death, or expansion of each of these cells controls the availability of this antigen-binding structure to the adaptive immune system. This is the heart of the clonal selection theory first proposed by Burnett in the 1950s. Self-reactive cells need to be deleted or retasked shortly after their birth. This process takes place in the bone marrow for B cells and the thymus for T cells. The anatomy of these two sites is different in keeping with

the dramatically different recognition mode employed by B and T cells. First we discuss the bone marrow space, followed by the functional anatomy of the thymus.

B Cell Development in the Bone Marrow

Immature B cells express surface BCRs composed of surface immunoglobulin noncovalently complexed to the signal transducing subunits Ig α and Ig β .⁵² The majority of immature B cells are reactive to self-antigens and even display “polyreactivity,” meaning that they produce antibodies that bind not just one but many self-antigens.⁵³ These auto-reactive cells are mostly lost from the repertoire in two checkpoints—the encounter of immature B cells with antigens in the bone marrow or by newly matured B cells on entry into secondary lymphoid tissues.⁵³ Checkpoint 1 depends on antigen display in the bone marrow. If BCRs on immature B cells encounter surface immobilized antigens on bone marrow cells or extracellular matrix, they will undergo apoptosis. The second source is the blood. The bone marrow parenchyma is bathed in blood plasma antigens due to fenestrated endothelial cells lining bone marrow sinusoids. When soluble antigens bind to their BCRs, they may undergo apoptosis if the antigen is multivalent and cross-links the BCR, inducing strong signaling. If the antigen is monovalent, the B cell may become anergic—a form of nonresponsiveness that is induced by weaker signaling through the BCR. In the second checkpoint newly matured B cells that have egressed from the bone marrow will encounter antigens on a variety of cells. For example, DCs present intact antigens to B cells⁵⁴ and because DCs sample many tissue antigens, this may provide a wider array of tissue-specific self-antigens to check against the BCR. These selection checkpoints decrease the frequency of self and polyreactive B cells by greater than 10-fold, but some polyreactive B cells persist in the repertoire. Polyreactivity may contribute to pathogen recognition, as recently shown for neutralizing antibodies to low-density envelope glycoprotein of HIV.⁵⁵ Thus the adaptive immune system may always need to tolerate some self-reactivity to defend us against the universe of pathogens.

T Cell Development in the Thymus

T cell precursors arrive in the thymus and initiate TCR gene rearrangement in this microenvironment. The thymus is an epithelial organ formed during development from the third pharyngeal arch. Histologically, the tissue has a clearly distinguishable cortex, medulla, and vascular corticomedullary junction.⁷ Figure 19-1 is adapted from a recent paper examining the dynamics of T cell selection in the thymus.⁵⁶ It shows fluorescence staining with *Ulex europaeus* antigen-1 (UEA-1) lectin, a marker for the thymic medulla, on the left side and major histocompatibility complex (MHC) class II antigen in the thymic cortex on the left side. The stepwise path of thymocyte migration is outlined on the left panel. Early CD4 and CD8 negative progenitors enter via postcapillary venules at the corticomedullary junction (step 1) and migrate to the subcapsular region of the cortex, where TCR gene rearrangement takes place and CD4 and CD8 become expressed on the surface of immature T cells, also called *thymocytes* (step 2). These cells then migrate

Figure 19-1 Section of mouse thymus stained with *Ulex europaeus* antigen-1 (UEA-1) lectin (left) or anti-major histocompatibility complex (MHC) class II (right) visualized with immunofluorescence microscopy. The UEA-1 staining is strongest in the medulla but also highlights the capsule and stroma of the cortex. The cortical thymic epithelial cells are strongly positive for MHC molecules, which allow negative and positive selection of thymocytes. (Images courtesy Richard Lewis, Stanford University.⁵⁶)

randomly among thymic epithelial cells in the cortex sampling self-MHC-peptide complexes (step 3). If they express a TCR that recognizes self-MHC-peptide complexes with low affinity, they will undergo “positive selection.” Positively selected thymocytes then mature into CD4⁺ or CD8⁺ positive cells that migrate to the medulla under control of CCR7 ligands⁵⁷ (step 4). Medullary thymic epithelial cells express a transcription factor called *AIRE* that mediates expression of a number of tissue-specific genes by amplifying expression from poorly expressed chromatin regions.⁵⁸ Rare patients lacking expression of *AIRE* have a complex autoimmune syndrome characterized by polyendocrinopathy and other tissue-specific autoimmune diseases. The hypothesis is that *AIRE*-mediated transcription of otherwise tissue-specific genes in thymic epithelial cells promotes negative selection of some autoreactive T cells and may also promote generation of tissue antigen-specific regulatory T cells (step 5). Conventional positive selection requires Ras activation on intracellular membranes, whereas stronger Ras activation at the plasma membrane mediates negative selection.⁵⁹ Regulatory T cell generation requires signaling through protein kinase C- θ and c-Rel transcription factors.⁶⁰ The small percentage of thymocytes that express a TCR that pass both positive and negative selection downregulate CD69 and S1PR1 and exit the lymph nodes as naïve “conventional” T cells (step 6).

SECONDARY LYMPHOID TISSUES: SITES WHERE ANTIGEN FINDS RARE SPECIFIC T AND B CELLS

The frequency of naïve T cells that recognize any particular antigen is so low that it has been challenging to estimate. Recently, enrichment methods using antibody-coated magnetic beads have been developed to assist direct measurement of precursors by flow cytometry with high-avidity MHC-peptide-based probes known as *tetramers*.⁶¹ The number of cells specific for commonly used model antigens is approximately 500 in most mouse strains when pooling cells from all secondary lymphoid tissues (spleen and lymph nodes). There are approximately 500 million total CD4⁺ T cells in these tissues, such that antigen-presenting DCs need to make contact with a million irrelevant T cells to find one specific T cell. Thus a small number of antigen-positive DCs early in an infection must have access to highly

concentrated swarms of T cells in secondary lymphoid tissues to sample enough T cells to find a few specific precursors to activate and expand. As described earlier, this search process is initially random but may become more directed and efficient as a response progresses. Although naïve T cells recirculate in an unbiased manner through secondary lymphoid tissues, the antigen-carrying cells, primarily DCs, have a high degree of regional bias in their movement, such that they are thought to relay information about both innate immune stimulation and tissue of origin of antigens.

Once antigen-specific T cells come into contact with DCs they form immunologic synapses; integrate signals through the T cell receptors and co-stimulatory ligands, which represent part of the innate immune system contribution to T cell activation; and divide more than 20 times with short cell cycle times of approximately 6 hours.⁶² Expansion of CD8⁺ T cells, which give rise to cytotoxic effector cells, is greater in general than for CD4⁺ T cells, which give rise to various types of helper T cells. After expansion, which peaks around day 7 to 10, the infectious agent is often eradicated and most of the effector T cells undergo apoptosis. The flulike symptoms associated with viral infections are due to cytokines produced by the dividing and differentiating T cells.

Because primary adaptive responses take a week or longer to develop, the host is dependent on innate immune mechanisms like natural antibodies, neutrophils, interferons, and natural killer cells to control the infection until sufficient numbers of effector T cells are generated. Thousands of the expanded T cells that survive after the pathogen is destroyed become memory cells.⁶³ Although the process of asymmetric division may contribute to establishment of memory and effector cells, linear models in which memory cells develop from effector cells are supported by fate mapping experiments demonstrating that functional memory can arise from effector T cells that expressed granzyme B, a cytotoxic effector molecule.⁶⁴

There are two subsets of memory T cells: (1) central memory cells that express L-selectin, CCR7, and LFA-1 and recirculate via secondary lymphoid tissues and (2) effector memory cells that lack L-selectin and CCR7 but may express P- and E-selectin ligands and other chemokine receptors such as CXCR4, CCR5, CCR4, and/or CCR9.⁶⁵ These effector memory cells migrate to peripheral sites of inflammation and are equipped for rapid effector function

if they encounter antigen. Memory cells respond rapidly to recurrence of the same infection and together with antibodies rapidly eradicate that same agent if it is encountered a second time. These memory cells may also cross-react with other pathogens, and depending on the degree of cross-reaction, this type of response can result in rapid clearance of a new pathogen or sometimes an impaired response.

Antigens from Blood Are Detected Most Efficiently in the Spleen and Liver (Portal System)

The spleen is a large visceral organ that filters approximately 5% of the cardiac output. The red pulp is an important location for removal of aged red blood cells from the circulation. The red pulp also contains many macrophages that specialize in this clearance process⁶⁶ and DCs that come into direct contact with naïve T cells that are in the blood. The function of these red pulp DCs is not known. Most attention has been focused on the white pulp nodules and the marginal zone as sites of T cell–DC interaction and antigen capture, respectively (Figure 19-2, left). Blood flows into the spleen via an artery that splits into arterioles that empty into venous sinuses in the marginal zone and red pulp (Figure 19-2, right). The blood is then re-collected into a venous system that drains to the liver, joining with the portal tract. The arterioles are surrounded by sheaths of T cells (the periarterial lymphoid sheath [PALS]) that make up the T cell zones of the white pulp. Bridging channels connect the red pulp, where lymphocytes leave the blood, to the PALS, where they migrate in a pertussis toxin-sensitive manner.⁶⁷ B cell follicles and the marginal zone then surround the PALS. Macrophages, DCs, and marginal zone B cells line the marginal zone, where they have direct

access to blood antigens. DCs that pick up antigens in the marginal zone migrate to the PALS within 9 hours.⁶⁸ A reticular fiber network connects the marginal zone to the PALS and allows soluble antigens from the blood to reach resident DCs in the PALS. Thus the spleen provides multiple opportunities to mount primary and recall responses to particulate or soluble antigens in the blood.

As mentioned earlier, the spleen drains into the liver. Immune responses in the liver are poorly understood, but this is an important site because many pathogens colonize the liver. Two blood circulations supply the liver: the portal vein with deoxygenated blood from the gut and spleen and the hepatic artery with oxygenated blood. These circulations mix in the liver sinusoids, a low-pressure network of blood spaces between sheets of hepatocytes connecting the portal tract and the central collecting vein. Thus most of the liver parenchyma appears as plates of hepatocytes alternating with blood carrying sinusoids (Figure 19-3, left). The liver is rich in a type of sessile macrophage called a *Kupffer cell* and patrolling lymphocytes, particularly natural killer T cells (Figure 19-3, right).⁶⁹ The major antigen-presenting cells in the liver are not Kupffer cells but the perivascular Ito cells.⁷⁰ The liver also plays an important role in the clearance of B cells mediated by therapeutic anti-CD20 antibodies that are used to treat patients with rheumatoid arthritis.⁷¹

Antigens from Mucosal Surfaces Are Detected Most Efficiently in Peyer's Patches and Mesenteric Lymph Nodes

The mucosal-associated lymphoid tissues include the tonsils, Peyer's patches, lamina propria, cryptopatches, and appendix. Peyer's patch and lamina propria DCs have different

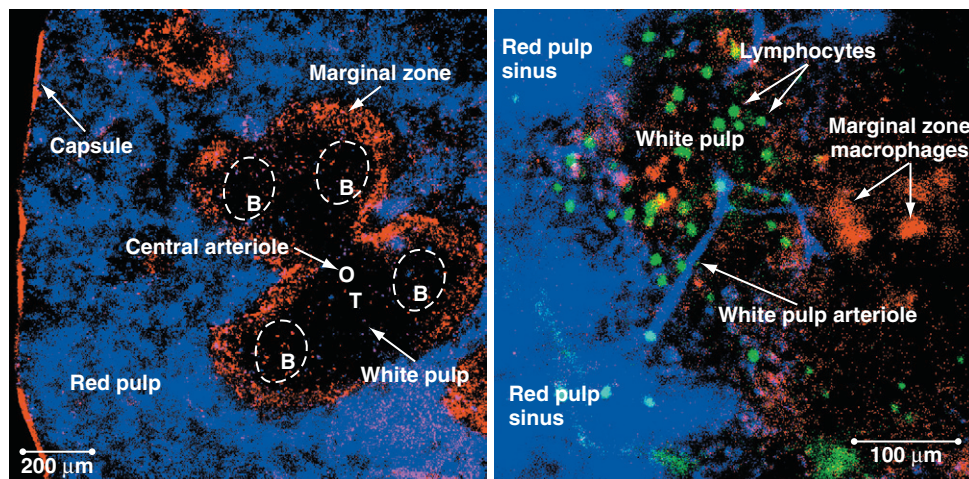

Figure 19-2 Organization of the spleen. *Left*, Tissue section from a mouse injected with low-molecular-weight (blue) and high-molecular-weight (red) fluorescent dextrans. The low-molecular-weight dextran labels the red pulp (blue) and the high-molecular-weight dextran labels macrophages in the marginal zone (red) such that the white pulp nodule containing approximately 10^9 lymphocytes per cm^3 is dark. The white pulp nodule forms around a central arteriole from which smaller arterioles branch to the red pulp sinuses. B and T cells are segregated into follicles (B cells) and the periarteriolar lymphoid sheath (T cells). (Scale bar 0.2 mm.) *Right*, Image of a live mouse spleen during injection of low-molecular-weight fluorescent dextran. The blood carrying the dextran passes through the white pulp in small blood vessels (arrows) emanating from the central arteriole (not shown) and connected to red pulp sinuses that rapidly fill with blood, which fills the marginal sinus but not the white pulp itself. In this image approximately 0.3% of the T cells in the PALS are labeled with a fluorescent dye. These areas are packed with T and B cells. Marginal zone macrophages and B cells have direct access to blood to capture pathogens. White pulp lymphocytes are not in direct contact with blood and need antigen presentation by cells that migrate from the marginal zone or antigens that are delivered to dendritic cells via reticular fibers.¹⁰¹ (Scale bar 0.1 mm.) (Courtesy Janelle Waite, New York University.)

Figure 19-3 Microcirculation and immune cells in liver. *Left*, Intravital imaging of blood space in mouse liver. Confocal imaging of hepatocytes (green autofluorescence) and blood space (red fluorescent dextran). The flow pattern is toward the center of the image panel. *Right*, Intravital imaging of NKT cells (bright green) and SIGN R1⁺ Kupffer cells in liver sinusoids (dark spaces) between hepatocytes (faint green autofluorescence). The Ito cells would also be lining the sinusoids, but on the other side of the endothelial cells in the space of Disse. (Courtesy Tom Cameron, New York University.)

mechanisms for sampling the contents of the gut lumen. Peyer's patches are composed of large B cell follicles with smaller T cell zones (Figure 19-4, top and bottom right). They have high endothelial venules that allow efficient entry of naïve T and B cells, as well as memory cells with gut homing phenotypes. The large size of the follicles in the Peyer's patches causes a domelike effect with the epithelium

protruding into the lumen. Some of the microvilli-laden absorptive epithelial cells in this dome region are replaced by smooth-surfaced M cells. These cells act as relay points for entry of enteric pathogens into the dome region of Peyer's patches where a population of CCR6⁺ DCs efficiently presents pathogen-related antigens to induce rapid local T cell responses⁷² (Figure 19-4, bottom left). In contrast

Figure 19-4 Gut-associated lymphoid tissues. *Top right*, Immunofluorescence image of Peyer's patch with B cells in green and T cells in red.¹⁰² *Bottom right*, A similarly oriented view of Peyer's patches from mouse in which CCR6⁺ dendritic cells also express GFP due to targeting of *gfp* to CCR6 locus.⁷² *Left*, Images of CD11c⁺ dendritic cells (DCs) in the tips of microvilli in the terminal ileum after exposure to *Salmonella* bacteria. The DCs extend processes through the epithelial layer to assist bacterial uptake.¹⁰³ The CCR6⁺ DCs rather than the CX3CR1⁺ lamina propria DCs appear to be the most important for the T cell response to *Salmonella* antigens.

to the Peyer's patches, the core of the villi in the terminal ileum is populated by activated T cells, plasma cells, DCs, and macrophages. The DCs migrate to mesenteric lymph nodes, where they present antigens to stimulate production of regulatory T cells and effector T cells to balance gut tolerance and immunity.⁷³ CX3CR1⁺ macrophages actively sample the gut contents and then may present antigens to effector and regulatory T cells that patrol the lamina propria⁷⁴ (Figure 19-4, bottom left). The gut presents a barrier between the host and billions of commensal bacteria and food antigens. There are also many pathogens—bacteria, viruses, protozoans, and worms—that exploit this niche. This is a rapidly developing area of research and is touched on again in the context of T cell differentiation.

Antigens from Other Tissues and Solid Organs Are Detected in Peripheral Lymph Nodes

An extensive network of peripheral lymph nodes filters lymph from the skin, visceral organs, and nervous system. Lymph is composed of fluid that leaves blood vessels and then must be collected from the tissues in afferent lymphatic vessels, passes through at least one lymph node, exits the lymph node as efferent lymph, and is returned to the blood via the thoracic duct. The afferent lymphatics of a lymph node connect to the capsule of the node and drain

into the subcapsular sinus, which contains many macrophages (Figure 19-5). The floor of the subcapsular sinus covers the lymph node parenchyma and is the point of origin of the reticular fiber network that connects to the high endothelial venules and medullary cords, where cells move from the parenchyma into the efferent lymph. Lymph does not come into direct contact with cells in the parenchyma, but cells lining the reticular fibers and a space between the high endothelial venules and the reticular fibroblast sheath are exposed to lymph fluid.³⁶ The parenchyma is divided into T and B cell zones defined by CCL19/21 and CXCL13 producing stroma (see Figure 19-5). DCs migrate from peripheral tissues in a CCR7-dependent manner and join networks of DCs in the T cell zones with scattered cells in the follicles.³⁵ Emigrant DCs have been reported to array around high endothelial venules, where they are efficiently encountered by newly extravasated T and B cells. Antigen-positive DCs have been shown in experimental models to stop both B and T cell migration during antigen encounter.^{45,54} These immunologic synapses, discussed earlier, play an important role in antigen transfer for B cells and for priming of proliferative response in T cells. It has been noted that different populations of DCs such as dermal DCs and Langerhans cells actually populate different subregions of the T cell zones, but the significance of this is not clear.

Figure 19-5 Lymph node schematic and dendritic cell morphologies. Schematic: B, B cell follicles; T, T cell zone; M, Medullary cords. Other structures are labeled. Lymph enters via the afferent lymphatics and exits via the efferent lymphatics. T cells enter the lymph node via the high endothelial venules and exit via medulla to the efferent lymphatic. Intravital microscopy-based images of dendritic cells in lymph nodes of CD11c-YFP marker mice are linked to a schematic of the lymph node. (All scale bars 50 μ m.) (From Lindquist RL, Shakhar G, Dudziak D, et al: Visualizing dendritic cell networks *in vivo*, Nat Immunol 5:1243-1250, 2004.)

Peripheral Tolerance Induction under Steady-State Conditions

Lymph nodes are associated with peripheral tolerance induction. DCs' presentation of antigens in the steady state induces proliferation of T cells that are then deleted or anergic by 7 days.⁷⁵ This process may be particularly important to tissue-specific antigens that are not present in the thymus in the steady state.⁷⁶ It is known that low-affinity self-antigens can escape peripheral tolerance induction by this mechanism.⁷⁶ Low-affinity self-antigen-specific T cells that are then activated in the context of infection by a pathogen with strong innate stimulation may then induce tissue-specific autoimmunity.⁷⁶

Regulatory T Cells Reduce Autoreactivity by Inhibiting Immunologic Synapse Formation

Regulatory T cells are CD25⁺ IL-2 dependent T cells that express the transcription factor FoxP3 and have the ability to suppress immune responses to tissue-specific self-antigens.⁷⁷ These cells represent another layer in redundant mechanisms to prevent autoimmune attack by adaptive immunity. One way in which regulatory T cells function is to block immunologic synapse formation between T cells and autoantigen-presenting DCs.⁷⁸ This mechanism appears to operate on low-affinity self-antigens that are the most likely type of self-reactive T cell to escape other peripheral tolerance mechanisms. Prevention of long-lived T cell–DC interactions may reduce proliferation and cytokine production by autoreactive T cells.

Changes in the Lymph Node during Infection/Vaccination

Infection or vaccination in tissues induces a strong reaction in draining lymph nodes. Innate signals trigger production of inflammatory cytokines that lead to increased blood flow, increased adhesion molecule and chemokine expression to increase T and B cell entry, and suppression of T and B cell exit by downregulation of S1PR1.⁷⁹ DCs in reactive lymph nodes express higher levels of co-stimulatory ligands such as CD80 and CD86 and promote robust proliferation, survival, and differentiation of antigen-specific T cells. T cells that are activated in the lymph nodes regain expression of S1P1 after 3 to 4 days and a new repertoire of homing molecules and migrate to effector sites.

Tissue Environment of Immature Dendritic Cells Determines T Cell Imprinting

When T cells are activated in lymph nodes, the repertoire of homing molecules expressed by the activated effector T cells is determined in part by the origin of the DC.⁸⁰ DCs arise from a common monocyte-like precursor that migrates into tissues via the blood. DCs that drain from the gut produce retinoic acid from vitamin A. Following maturation and migration to draining lymph nodes, these DCs secrete retinoic acid, which induce activated T cells to express gut-homing chemokine receptors like CCR9 and gut-specific integrins like $\alpha 4\beta 7$. Because gut-associated

postcapillary venules express MAdCAM and present CCL25 (a CCR9 ligand), these effector T cells will tend to home to the gut. In the absence of retinoic acid produced by gut-derived DCs, the signals induced by skin-derived DCs favor expression of ligands for E- and P-selectin and CCR4 on T cells.⁸⁰ Because endothelial cells of skin-associated postcapillary venules express P-selectin and present CCL17, these T cells will tend to home to inflamed skin. Recently, it has been shown that DCs in the skin metabolize vitamin D to generate a signal for T cell expression of CCR10, which allows these cells to migrate to the epidermis in response to CCL27. Although DCs will strongly skew T cells to home back to the sites from which the DCs migrated, the expression of homing receptors and chemokines on lymphocytes also has a stochastic component, which means that these effector cells and memory cells will also show up in diverse peripheral sites scattered throughout the animal—giving effector T cells their ability to appear in any tissue at any time. Overall, these results show that DCs sense their tissue environment and innate immune activation signals in the process of shaping T cell responses.

Germinal Center Reactions: Sites of Antibody Affinity Maturation and Class Switch Recombination

Low-molecular-weight antigens that enter the subcapsular sinus are directly accessible to B cells.⁸¹ Particulate antigens are captured by subcapsular macrophages and transferred to B cells, which then mediate their transport to follicular dendritic cells in a nonantigen specific process requiring complement receptors.⁸² B cell activation by antigens in conjunction with co-stimulation via complement receptor or other forms of innate immune stimulation can lead to immediate proliferation of the B cells and the formation of plasma cells producing IgM antibodies from daughter cells.⁸³ Specific T cell help promotes the formation of germinal centers within the B cell zone of any secondary lymphoid tissues. Germinal centers are roughly spherical collections of hundreds of antigen-specific B cells that undergo interaction with follicular T helper cells in the light zone and proliferation in the dark zone⁸⁴ (Figure 19-6). The light zone is populated by stromal follicular DCs, which unlike conventional DCs are of nonhematopoietic origin, and follicular helper T cells. Follicular DCs use complement receptors to hold immune complexes on their surface for sampling by antigen-specific B cells. The follicular helper T cells provide help to B cells that maintain or increase their affinity for antigens and can also provide cytokine signals to promote class switching. Intravital microscopy studies demonstrate that germinal centers are dynamic open structures in which antigen-specific B cells are continuously in motion and follicular DCs are accessible to interaction with B cells having diverse receptor specificity.⁸⁵ Thus antigen-specific B cells can be recruited into germinal center reactions at any time in the process and can compete openly with B cells that were present earlier.⁸⁶ Interactions between follicular helper T cells and centrocytes in the light zone are also highly dynamic and depend on the SAP adapter protein.⁸⁷ T cells help control interzonal migration and affinity maturation.⁸⁴

Figure 19-6 Germinal center in living mouse lymph node. A germinal center was induced by vaccination after introduction of fluorescent antigen-specific B cells and antigen. Follicular dendritic cells were labeled with FDC-M1 antibody conjugated to a red fluorescent dye. Reticular fibers, which serve as antigen conduits into the follicle, are labeled blue. The germinal center (GC) is outlined and divided into a dark zone (DZ) containing aggregated centroblasts (green) and a light zone (LZ) containing loosely aggregated centrocytes, follicular dendritic cells (FDC-M1⁺), and follicular T cells (not shown). The surrounding follicle is densely packed with bystander B cells (not shown), which often enter and traverse the LZ. Green cells in the medullary region are plasma cells produced in the germinal center reaction. (From Schwickert TA, Lindquist RL, Shakhar G, et al: *In vivo* imaging of germinal centres reveals a dynamic open structure, *Nature* 446:83–87, 2007.)

Because most somatic mutations destroy the BCR or lower its affinity, there is a large amount of apoptosis in the germinal center in addition to proliferation to provide substrates for mutations.

TERTIARY LYMPHOID TISSUES: GENERATED AT SITES OF CHRONIC INFLAMMATION

Tertiary lymphoid tissues resemble secondary lymphoid tissues in many respects but are formed in the adult in response to chronic inflammation in locations where such tissues do not exist in steady-state conditions. The induction of tertiary lymphoid tissues can be compared with the formation of lymph nodes during normal development. Normal lymph node development involves the colonization of connective tissues in characteristic vascular nexuses by ROR γ t-dependent, CD4⁺, lymphotoxin-positive lymphoid tissue inducer cells.⁸⁸ These cells use surface lymphotoxin and TNF to induce local stromal cells to express ICAM-1 and VCAM-1 and produce CCL19/21 or CXCL13, leading to development of lymph node stroma with a reticular fiber conduit system that is integrated into the developing lymphatic vessel system. Thus steady-state presentation

of inflammatory cytokines plays a key role in this process. This normal process can also be recapitulated in the adult because chronic inflammation induces production of TNF and lymphotoxin in normal tissues, leading to the induction of stromal cells to form organized follicles and T cell zones within the inflamed tissues. Induction of stromal cells to produce CCL19/21 and/or CXCL13 is probably important in this process because transgenic expression of CXCL13 in ectopic locations in mice leads to formation of fully developed B cell follicles in these tissues.⁸⁹ Thus B cells may have a particular capacity to induce tertiary lymphoid tissues. The efficacy of anti-TNF therapies in autoimmune disease may relate to the suppression of such tissues.⁹⁰

Tertiary lymphoid tissues are often associated with autoimmune diseases including rheumatoid arthritis and the local infiltration of naïve T cells in an area with high concentrations of tissue-specific self-antigens, and innate stimulation may promote progression of disease by recruiting new T and B cell specificities into the autoimmune process.⁹¹ Breaking this cycle may be a key target of anticytokine and anti-B cell therapies that have been remarkably effective and are discussed in later chapters.

FOUR MAJOR TYPES OF EFFECTOR T CELLS

CD8⁺ effector T cells are generally cytotoxic and involved in killing of infected cells. CD8⁺ T cell responses can be initiated without CD4⁺ T cells' help, but CD4 T cell help is required for effective CD8⁺ T cell memory.⁹² Important transcription factors for effector CD8 T cell differentiation are Tbet and eomesodermin.⁹³ Three major types of effector CD4⁺ T cells are recognized. The first defined axis for CD4 T cell differentiation was between IFN- γ -producing T cells expressing the master transcription factor Tbet and IL-4-producing T cells using the master transcription factor GATA3.⁹⁴ The IFN- γ -producing cells are referred to as *Th1 cells*, which help inflammatory cytotoxic T cell and macrophage responses, and the IL-4-producing cells, called *Th2*, help antiparasitic B cell responses leading to IgE production and eosinophilic infiltration. The major cytokines that initiate Th1 responses are IFN- γ and IL-12 in the absence of IL-4, whereas IL-4 is the major cytokine that initiates the Th2 program. Recently it has been appreciated that a third type of effector T cell produces IL-17 and is important in many inflammatory diseases. Differentiation of these Th17 cells requires the nuclear hormone receptor ROR γ t.⁹⁵ The cytokine conditions that lead to development of Th17 cells are transforming growth factor (TGF)- β plus IL-6, with IL-23 for maintenance.⁹⁶ The role of TGF- β places Th17 cells on the same axis with induced regulatory T cells, with the deciding factor being the presence of IL-6 or IL-1 β to favor Th17 over Treg induction.⁹⁷ These are highly proinflammatory T cells that trigger recruitment of neutrophils to combat extracellular bacterial infections. Recently, the generation of gut-associated Th17 cells in mice has been linked to a single species of segmented filamentous bacteria.⁹⁸ The presence of the commensal bacteria improves the clearance of intestinal pathogenic bacteria that require a Th17 response, but it also leaves the host more susceptible to autoimmune arthritis.⁹⁹

SUMMARY

Adaptive immune responses have a degree of flexibility that is unparalleled in molecular recognition systems. This flexibility has a dangerous side that is constrained by anatomy and strong coupling to innate immunity. Autoimmune disease may result when weak points in tolerance mechanisms intersect with infection or tissue damage, leading the adaptive system to attack its own organs in a self-amplifying process of tissue destruction, inflammation, and inappropriate anatomic adaptation such as tertiary lymphoid tissue genesis. These processes are highly relevant to rheumatoid diseases. For example, a mouse model for autoimmune rheumatic disease called the *KRN transgenic mouse* develops a T cell- and B cell-dependent joint disease.⁹⁹ Strategies to break these cycles by attacking innate or adaptive immune system components nonspecifically have met with success, but more specific strategies may reduce negative consequences of general immunosuppression.¹⁰⁰

Autoimmunity

DWIGHT H. KONO •
ARGYRIOS N. THEOFILOPOULOS

KEY POINTS

Autoimmunity ranges from physiologic autoreactivity to overt autoimmune disease, in part reflecting the complexity of the immune system, the presence of multiple layers of tolerance mechanisms, and genetic heterogeneity.

Autoimmune diseases can be classified by extent of organ involvement (organ-specific to systemic), innate immune system requirements, and effector mechanisms, but each type of autoimmune disease has unique pathophysiologic characteristics.

Advances in defining the mechanisms underlying autoimmune diseases have been greatly facilitated by delineation of the innate and adaptive immune systems.

Susceptibility to autoimmune diseases is multifactorial involving genetic, environmental, gender, and other factors, with genetic predisposition usually playing a central role. Their contributions are typically heterogeneous, partial, and additive.

Animal models are critical for understanding the pathophysiology of autoimmune diseases, providing fundamental insights into genetic, mechanistic, and pathologic processes. Spontaneous animal models for most autoimmune diseases do not exist.

Progress in delineating pathways revealed many key players in autoimmune diseases that are of potential therapeutic relevance.

Autoimmune diseases represent a significant health burden for 3% to 9% of the general population, and rheumatology, perhaps more than any medical subspecialty, encompasses a broad array of such diseases involving a wide range of organ systems (Table 20-1).¹⁻³ Rheumatologists consequently have a substantial interest in defining the causes and pathophysiologic processes related to autoimmunity and in applying this information to the clinic.

The immune system must effectively defend against a diverse universe of pathogens while simultaneously maintaining tolerance to self-antigens. Recent advances have begun to clarify how this equilibrium is established and sustained and, importantly, have identified many critical factors and processes involved in the pathophysiology of autoimmune diseases. This chapter seeks to provide a general overview of autoimmunity covering the definition of the term, general tolerance mechanisms for T and B lymphocytes, theories of how tolerance can be breached, and ways in which genetic and environmental factors have been implicated to break tolerance and produce disease. Emphasis is placed on manifestations and mechanisms related to rheumatologic pathoses.

DEFINITION AND CLASSIFICATION OF PATHOGENIC AUTOIMMUNITY

Autoimmunity, the immune response against self, evokes the specter of “horror autotoxicus,” a term coined by Paul Ehrlich at the turn of the 20th century to depict the perceived disastrous consequences of this condition.⁴ In fact, autoreactivity is more nuanced, ranging from a low “physiologic” level of self-reactivity that plays an essential role in lymphocyte selection and maintenance of normal immune system homeostasis, to an intermediate level of autoimmunity including autoantibodies and tissue infiltrates unassociated with clinical consequences, to pathogenic autoimmunity associated with immune-mediated dysfunction or injury. From the clinical perspective, it is the transformation to pathogenic autoimmunity that demarcates significant from insignificant self-reactivity.

The diagnosis of an autoimmune disease is generally based on the presence of adaptive immune system–mediated pathology caused by self-reactive antibodies or T cells. For many common autoimmune diseases, more definitive evidence for an autoimmune etiology has come from studies showing transfer of disease by autoantibodies or self-reactive T cells and animal models exhibiting congruent characteristics. There are, however, no universally accepted criteria and some less well-characterized diseases, currently considered to be autoimmune, may turn out to have other causes.

An example of diseases that exhibit some characteristics of autoimmunity yet are distinct in their pathogenesis are the so-called autoinflammatory syndromes.⁵⁻⁷ These are mostly rare monogenic disorders typified by intermittent bouts of fevers, rash, serositis, and arthritis caused by defective control of basic inflammatory mechanisms. Included are familial Mediterranean fever, the cryopyrinopathies, hyperimmunoglobulinemia D with recurrent fever, familial cold urticaria, and Blau syndrome. These disorders could be considered one end of a broader definition of autoimmunity, but because their pathophysiology is mediated entirely through the innate arm of the immune system, they are currently classified as a separate entity. Nonetheless, the possibility of a less stringent demarcation has been suggested by disorders such as Behçet’s syndrome, systemic juvenile rheumatoid arthritis, and Crohn’s disease, which appear to manifest both autoinflammatory and autoimmune features.

Autoimmune diseases are classified as systemic or organ-specific depending on the extent of their clinicopathology (Table 20-2). The systemic category includes systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), scleroderma, primary Sjögren’s syndrome, dermatomyositis, and systemic vasculitis. In this case, autoimmunity targets

ubiquitously expressed self-antigens and end-organ injury is typically mediated by autoantibodies and, less commonly, T cells. Contrastingly, in organ-specific diseases the self-antigens are typically cell or tissue specific in location or accessibility and end-organ damage can be mediated by antibodies and/or T cells. Some of the more notable examples in this group, which span virtually all organ systems, include Hashimoto's thyroiditis, Graves' disease, multiple sclerosis (MS), type 1 diabetes mellitus (T1DM), antiphospholipid syndrome (APS), pemphigus vulgaris, autoimmune hemolytic anemia, idiopathic thrombocytopenic purpura, and myasthenia gravis. It should be noted, however, that although the distinction of systemic and organ-specific disorders provides a conceptual framework, the pathophysiologies of autoimmune diseases are more diverse than might be implied by this simple classification. Autoimmune diseases can also be classified by hypersensitivity reaction type based on the mechanism of adaptive immune system-mediated injury.⁸ See later discussion in the chapter.

ANIMAL MODELS OF AUTOIMMUNITY

Much of what is known about the immune system and autoimmunity has been derived from studies in animals, particularly the mouse, which has an immune system and genome composition similar to humans. There are many well-characterized autoimmune models, and investigators can manipulate their genomes and immune systems, test interventions, and modify their environments. Animal models of autoimmune disease comprise three main types on the basis of their derivation: (1) spontaneous, (2) genetically modified, and (3) induced. Table 20-3 lists some of the more common or notable types (see also Chapter 28).

Within the spontaneous group are models of SLE, RA, and type 1 diabetes mellitus. The lupus-prone strains commonly develop anti-DNA and immune-complex-mediated kidney damage, but they also possess unique phenotypic characteristics and differ in the genes underpinning susceptibility.⁹ The SKG arthritis model is a spontaneous,

inflammatory, and erosive arthritis caused by a ZAP-70 mutation that, similar to RA, is associated with rheumatoid factor (RF) and antibodies to citrullinated proteins.¹⁰ The NOD mice and BB rats develop T1DM caused by T cell-mediated destruction of β -islet cells.¹¹

The genetically modified group, encompassing transgenic, site-directed genetic replacement (gene knockout or knockin), and ENU-mutagenized mice, is by far the largest, with more than 80 different models of lupus alone, as well as many models of organ-specific diseases, particularly T1DM and MS.^{9,11} The lupus models, mostly single-gene knockout or transgenic mice, have provided a wealth of information related to immune tolerance and disease pathogenesis. Some examples are (1) confirmation of human SLE gene associations and elucidation of mechanisms (e.g., C1q and Fc γ RIIb knockout mice), (2) discovery of novel mechanisms (e.g., altered mRNA regulation in *Sanroque* and miR-17-92 transgenic mice), and (3) identification of new pathways relevant to therapy (e.g., BAFF transgenic). An example of an arthritis model created by genetic modification is the K/BxN mouse, a B6 \times NOD hybrid expressing a transgenic T cell receptor, named KRN, that recognizes a bovine RNase peptide on MHC class II A^k.¹² These mice develop an acute severe inflammatory arthritis caused by antibodies to glucose-6-phosphate isomerase (GPI), an antigen that, although intracellularly and ubiquitously expressed, is mainly accessible to antibodies in joints. GPI is not a major target in RA or other arthritides, but the model has nevertheless been useful for investigating inflammatory mechanisms in arthritis.¹³ Other genetically modified models of spontaneous arthritis include the HTLV-I tax transgenic, the TNF transgenic, the IL-1ra transgenic, the IL-1 transgenic, and a gain-of-function knockin mutant of CD130, a signaling component for several cytokines including IL-6, IL-11, IL-27, and LIF.¹⁴ Scientists have developed several genetically modified models of T cell-mediated organ-specific disease. They consist of TCR transgenic T cells that recognize tissue-specific antigens in organs such as the brain and pancreatic islets or employ a slightly modified version in which mice are double transgenic for both an antigen expressed in a tissue of interest and the corresponding TCR.¹⁵⁻¹⁸ By allowing analysis of single autoreactive T cell clones, these models have yielded considerable insights into tolerance mechanisms and disease pathophysiology. Similarly, researchers have developed autoreactive B cell receptor transgenics or knockin models that have been crucial for defining B cell tolerance mechanisms.¹⁹⁻²⁵

The induced models encompass a wide variety of both systemic and organ-specific diseases. More commonly studied models of systemic disease include tetramethylpentadecane (TMPD, also called *pristane*)-induced autoimmunity, mercury-induced autoimmunity, and chronic graft-versus-host disease.²⁶⁻²⁸ All bear similarities to human SLE in producing antinuclear antibodies and immune complex deposits, but they differ in pathophysiology and strain susceptibility. For the induced models of organ-specific diseases, a common approach is to immunize rodents with a self-antigen or closely related peptide or foreign-antigen, plus a strong adjuvant, usually complete Freund's. This approach makes it possible to induce autoimmunity in virtually all organ systems and to produce diseases mediated by cellular and humoral mechanisms. Some of the more

Table 20-2 Classification, Mechanisms, and Models of Autoimmune Diseases

Syndrome	AutoAg	Consequence	Hypersensitivity Type*	Animal Model (Example)
Systemic				
Antiphospholipid syndrome	β 2-GP1 (apoH)	Vascular thrombosis, recurrent miscarriages	II	(NZW \times BXSb)F1
Microscopic angiitis	p-ANCA (MPO)	Glomerulonephritis, leukocytoclastic vasculitis, mononeuritis multiplex, lung inflammation	III	Anti-MPO
Granulomatosis with polyangiitis	c-ANCA (PR3)	Vasculitis of kidney, upper airway, and lungs	III	None
Cryoglobulinemia	Unknown	Cutaneous vasculitis, glomerulonephritis	III	MRL- <i>Fas</i> ^{lpr}
SLE	Nucleic acids	Glomerulonephritis, skin lesions, arthritis, CNS lupus, and others	III	MRL- <i>Fas</i> ^{lpr} , BWF1, BXSb, NZM2410
Systemic sclerosis	Unknown	Fibrosis of multiple organs	III	Tsk/+ mice, bleomycin-induced
RA [†]	RF IgG immune complexes; citrullinated proteins; other joint antigens	Arthritis and associated manifestations rheumatoid nodules, rheumatoid lung, Felty's syndrome	III	CIA, PGIA, AA, SKG, K/BxN, BXD2 mice
Organ-Specific				
Graves' disease	TSH receptor	Stimulation of receptor; hyperthyroidism	II	EAT
Myasthenia gravis	ACh receptor	Receptor blockade/modulation; neuromuscular paralysis	II	EAMG
Autoimmune hemolytic anemia	RBC surface Ag	C' and Fc γ R-mediated cell destruction; anemia	II	NZB
Idiopathic thrombocytopenic purpura	Platelet integrin GpIIb/IIIa	Thrombocytopenia; purpura, bleeding	II	(NZW \times BXSb)F1
Goodpasture's syndrome	Type IV collagen* and other basement membrane Ags	Pulmonary hemorrhage, glomerulonephritis	II	Anti-CIV, antilaminin
Pemphigus vulgaris	Epidermal cadherin (Dsg3)	Bullous skin lesions	II	Anti-Dsg3
Neonatal lupus	Ro/La	Cutaneous LE, heart block	II	None
T1DM	Pancreatic β -cell antigens	Pancreatic islet inflammation, diabetes	IV	NOD, BB
Multiple sclerosis	CNS antigens; MBP, PLP, MOG in animal models	Progressive CNS inflammation and paralysis	IV	EAE, Theiler's virus infection

*Most likely hypersensitivity type.

[†]Both systemic and organ-specific.

AA, adjuvant arthritis; ACh, acetylcholine; ANCA, anti-neutrophil cytoplasmic antibody; anti-CIV, antitype IV collagen; anti-Dsg3, antidesmoglein 3; β 2-GP1, β 2-glycoprotein 1; CIA, collagen-induced arthritis; EAE, experimental autoimmune encephalomyelitis; EAMG, experimental autoimmune myasthenia gravis; EAT, experimental autoimmune thyroiditis; MBP, myelin basic protein; MOG, myelin oligodendrocyte glycoprotein; MPO, myeloperoxidase; PGIA, proteoglycan-induced arthritis; PLP, proteolipid protein; PR3, proteinase 3; RF, rheumatoid factor; TSH, thyroid stimulating hormone; other abbreviations are mouse strains.

commonly studied organ-specific models developed by this approach include collagen-induced arthritis (CIA), proteoglycan-induced arthritis (PGIA), and experimental autoimmune encephalomyelitis (EAE), but there are many others to thyroid, eye, gonad, nerves, neuromuscular junction (acetylcholine receptor), muscle, heart, adrenal gland, bladder, stomach, liver, inner ear, kidney, and prostate tissues. In certain susceptible strains of rats, a progressive inflammatory erosive arthritis called *adjuvant arthritis* can also be induced by intradermal injection of complete Freund's adjuvant or by mineral oil components of Freund's adjuvant such as TMPD. Other induced models of arthritis include streptococcal cell wall and antigen-induced arthritis.¹⁴ Recently, arthritis characterized by synovial hyperplasia and ankylosis was reported in HLA-DR4 transgenic mice immunized with human citrullinated fibrinogen.²⁹

COMPOSITION OF THE INNATE AND ADAPTIVE IMMUNE SYSTEMS

The immune system comprises two major arms, innate and adaptive. The former is classically the initiator of immune responses to pathogens because of its capacity, on the one hand, to be activated by diverse pathogen-associated molecular patterns (PAMPs) expressed by microbes and, on the other hand, to activate the adaptive immune system through the production of proinflammatory factors and the presentation of antigens to lymphocytes.³⁰⁻³² The adaptive response adds more protection through clonal recognition of an almost limitless diversity of antigenic specificities, immunologic memory of previous antigenic encounters, and additional cellular and antibody-mediated mechanisms to eliminate or neutralize microbes and other pathogens. Both

Table 20-3 Partial List of Autoimmune Disease Models

Model	Autoimmune Disease	Species	Notable Characteristics
Spontaneous Variant			
MRL-Fas ^{lpr}	SLE	Mouse	Fas mutation, defective apoptosis, lymphoproliferation, human counterpart ALPS
(NZB × NZW)F1	SLE	Mouse	Female predominance
NZB	SLE, AIHA	Mouse	Anti-RBC
BXSB	SLE	Mouse	Yaa mutation (duplication of X chromosome containing <i>TLR7</i> gene on Y chromosome)
(NZW × BXSB)F1	SLE, APS, ITP	Mouse	Anticardiolipin, antiplatelet
BXD2	SLE, RA	Mouse	Lupus and inflammatory arthritis
SKG	RA	Mouse	ZAP-70 mutation
NOD	T1DM	Mouse	MHC (H-2 ^{g7}) similar to T1DM-predisposing HLA
BB	T1DM	Rat	Lymphopenia
Genetically Modified			
C1q ko	SLE	Mouse	Defective clearance of apoptotic cells
FcγRIIb ko	SLE	Mouse	Impair regulation of B cell and antigen-presenting cells
BAFF Tg	SLE	Mouse	Enhanced survival of B cells
TLR7 Tg	SLE	Mouse	Enhanced survival and activation of B cells and DCs
<i>Sanroque</i> mice (<i>roquin</i> gene)	SLE	Mouse	<i>Rc3h1</i> M199R mutation increases ICOS expression and Tfh cell expansion
miR-17-92 Tg	SLE	Mouse	miRNA-induced autoimmunity
K/BxN, TCR Tg	RA	Mouse	Arthritis mediated by anti-GPI
MBP-specific TCR Tg mice	MS	Mouse	Spontaneous autoimmune encephalomyelitis
Double Tg: anti-GP TCR and insulin promoter-GP (GP=LCMV glycoprotein)	T1DM	Mouse	Ignorant Tg T cells are activated by infection with LCMV causing insulinitis and diabetes
Induced			
TMPD (pristane)-induced autoimmunity	SLE	Mouse	IFN-α and TLR7 dependent
Hg-induced autoimmunity	SLE	Mouse, rat	IFN-γ dependent
Chronic graft-versus-host disease	SLE	Mouse	Parent into F1
Collagen-induced arthritis	RA	Mouse, rat	Autoimmunity to type II collagen
PG-induced arthritis	RA	Mouse	Autoimmunity to proteoglycan
Adjuvant arthritis	RA	rat	Inflammatory arthritis induced by complete Freund's adjuvant or mineral oil
EAE	MS	Mouse, rat	Autoimmunity to MBP, MOG, or PLP depending on MHC haplotype
EAT	Thyroiditis	Mouse, rat	Autoimmunity to thyroglobulin
EAMG	MG	rat	Autoimmunity to acetylcholine receptor

AIHA, autoimmune hemolytic anemia; ALPS, autoimmune proliferative syndrome; APS, antiphospholipid syndrome; EAE, experimental autoimmune encephalomyelitis; GPI, glucose-6-phosphate isomerase; ko, gene knockout; ITP, idiopathic thrombocytopenic purpura; MBP, myelin basic protein; MS, multiple sclerosis; mus, mouse; MOG, myelin oligodendrocyte glycoprotein; PLP, proteolipid protein; T1DM, type 1 diabetes mellitus; Tg, transgenic; TMPD, 2,6,10,14-tetramethylpentadecane.

systems use a large variety of immune-related molecules, cell types, and interactions among the various components to provide layers of protection that contribute to overall resistance to commensal and invading organisms. Similarly, prevention of self-reactivity is also effected by multiple inhibitory or deleting processes that, *in toto*, afford layers of safeguards against autoimmunity. The innate and adaptive immune systems are highly interconnected with activating and inhibitory feedback mechanisms operating in both directions.

Innate Immune System Composition

The main functions of the innate immune system include (1) the clearance of foreign and potentially detrimental self-materials through the recruitment, activation, and effector activity of immune cells; (2) activation of the complement pathways, and (3) triggering of the adaptive immune response (see also Chapter 18). A key feature of

the innate, and to some extent the adaptive, immune system is that it is activated by the engagement of pattern-recognition receptors (PRRs) that recognize common structures on pathogens and also a few self-molecules such as certain damage-associated molecular patterns (DAMPs) (e.g., heat shock proteins),³³ released during cellular stress, injury, or death. PRRs can be classified by their location into secreted, transmembrane, or cytosolic types.³¹ Secreted PRRs include collectins, pentraxins, and to some extent C1q, properdin, serum amyloid A, and mindin, which facilitate clearance of pathogens by promoting opsonization and complement activation.³⁴ Transmembrane PRRs that provide activating signals following engagement with the corresponding PAMPs include the Toll-like receptors (TLRs), several C-type lectin receptors (dectin receptors, mannose receptor, DC-SIGN), and *N*-formyl methionine receptors.³⁵

The TLRs are of particular interest because of their role in autoimmune diseases such as SLE.³⁶ They are a family of type I membrane proteins that contain a ligand-binding

ectodomain composed of 18 to 25 tandem leucine-rich repeats, a transmembrane region, and an intracellular cytoplasmic Toll/interleukin 1 receptor (TIR) domain through which they interact with two main adapters, MyD88 (all TLRs except TLR3) and TRIF (TLR3, TLR4).^{37,38} TLRs are either expressed as cell surface receptors where they recognize primarily bacterial products such as lipoteichoic acids (TLR1/2 heterodimer), lipoproteins (TLR2/6), lipopolysaccharide (TLR4), and flagellin (TLR5), or in the endolysosomal compartment where they bind different types of nucleic acids including dsRNA (TLR3), ssRNA (TLR7), and dsDNA (TLR9). The intracellular location of the nucleic acid-binding TLRs is thought to reflect both the optimal location for exposure to microbial nucleic acids, which are released in the endolysosomes following phagocytosis, and the necessity of avoiding activation by extracellular self-nucleic acids.³¹ Cell types express different combinations of TLR members, reflecting the role of specific TLRs in cell function (e.g., the endosomal TLRs recognizing nucleic acids are predominantly expressed in phagocytes and antigen-presenting cells).

The cytosolic PRRs include (1) RIG-I-like receptors (RLRs) that include RIG-I, a sensor for foreign uncapped 5'-triphosphate RNA and MDA5 that recognizes long dsRNA^{39,40}; (2) NOD-like receptors (NLRs) that recognize bacterial cell wall products^{41,42}; and (3) several DNA sensors, IFI16,^{43,44} LRRFIP1,⁴⁵ Ku70,⁴⁶ AIM2, and DNA-dependent RNA polymerase III, which does not detect DNA directly but transcribes AT-rich DNA to 5'uncapped 5'-triphosphate RNA that in turn activates RIG-I.^{7,32,47,48} The role of these cytosolic PRRs in autoimmune diseases has not yet been defined.⁴⁹

Collectively, engagement of the TLR and cytosolic PRRs activates immune cells through several signaling pathways that converge primarily to activate nuclear factor κ B (NF κ B)/cytokine or inflammasome programs. Furthermore, depending on the PRRs engaged, cell types activated, and site of activation, this system of receptors facilitates the generation of nuanced responses to a wide array of potential pathogens.⁵⁰

Major innate immune system cell types include macrophages, dendritic cells, neutrophils, plasmacytoid dendritic cells (pDC), natural killer (NK) cells, basophils, mast cells, and eosinophils. In addition, certain T lymphocyte subsets that express predominantly invariant antigen receptors that recognize microbial products such as certain $\gamma\delta$ -T cells⁵¹ and NK T cells⁵² might also be considered part of the innate system. Similarly, certain B lymphocyte subsets, including B1 and marginal zone B cells, have characteristics suggesting a lineage with innate properties (e.g., development from precursors early, but not late in life, the capacity for self-renewal and expression of primarily low-affinity polyclonal active IgM).

The innate response is also strongly influenced by non-hematopoietic cells including endothelial, stromal, fibroblast, and keratin cells that can elaborate proinflammatory factors following engagement of PRRs, injury, or activation by the adaptive immune system. Examples include, non-hematopoietic cells are required for NOD 1 receptor-mediated Th2 immune responses⁵³, synovial fibroblasts play a central role in RA⁵⁴, and keratinocyte secretion of CSF-1 after UV exposure promotes cutaneous lupus.⁵⁵

The complement system⁵⁶ comprises an immune surveillance system that interacts with, and promotes elimination of, modified host cells, cellular debris, and foreign entities (see also Chapter 23). This system is tightly interconnected with inflammatory, immune, and other pathways and because of this, often plays important roles in both autoimmune-inflammatory and autoimmune diseases.

Activation of the complement cascade occurs through the classical, alternative, and lectin pathways, which function in complement-mediated lysis (C5b-C9 attack complex), release of proinflammatory mediators (C3a, C5a), opsonization (C1q, mannose binding lectin), and B cell activation (iC3b, C3dg; activation of B cells via CR2). Complement is regulated by soluble factors (C1 esterase inhibitor, sMAP and MAP-1, C2 receptor inhibitor trispanning, factor H, factor H-like protein 1, and C4b-binding protein), as well as cell surface decay accelerators such as CR1 and DAF (CD55), inhibitors of the terminal complement complex (CD59, vitronectin, clusterin), carboxypeptidase-N, and CD46. Major functions are the killing and elimination of pathogens, initiation and amplification of inflammation, safe removal of apoptotic cells and material, interaction with TLR signaling and coagulation pathways, and in facilitating immune complex clearance, angiogenesis, and tissue regeneration. Importantly, complement enhances and modulates humoral and cellular immune responses by several mechanisms including C3dg opsonization of antigen that promotes both costimulation of B cells via complement receptor 2 (CR2) binding and the capture of antigen on follicular DC (FDC) by CR1/2; activation of the C5aR on immune cells; along with direct and indirect effects of complement components on T cell activation and differentiation.

Adaptive Immune System Composition

The main constituents that distinguish the adaptive from the innate immune response are the B and T lymphocytes, which express an expansive array of diverse antigen receptors (see also Chapter 19). In aggregate, the pool of lymphocytes is capable of recognizing virtually all antigens and, by the process of selection, lymphocytes with beneficial specificities can be expanded and retained. These properties allow the immune system to detect a manifold galaxy of foreign antigens and to respond rapidly and specifically to secondary challenges. T and B lymphocyte antigen receptors are created by the random recombination of a large number of variable region (V-D-J) gene segments and diversity-producing end-joining mechanisms in primary lymphoid organs. Furthermore, peripheral B cells can also increase specificity by somatic hypermutation and selection of higher affinity clones. The clonal nature of lymphocytes, bestowed by uniquely rearranged antigen receptors, is key to the exquisite discriminating power of the immune system. Clonality also extends to other characteristics such as cytokine production, surface receptors, and cell signaling molecules.

T cells play a central role in the adaptive immune response through elaboration of cytokines such as IFN- γ and TNF, IL-4, and IL-17, by providing essential signals to B cells in T cell-dependent humoral responses, as direct killers of cells, and by promoting inflammation in target

tissues (see also Chapter 13). Importantly, because of their clonal nature and the immune system's ability to neutralize specific self-reactive clones, they play a fundamental role in regulating autoreactivity. T cells arise in the thymus, where they transit through defined maturation stages and undergo positive and negative clonal selection.^{57,58} Thymic-derived T cell populations include the classical CD8 and CD4 $\alpha\beta$ T cells, $\gamma\delta$ T cells, NK T cells, natural regulatory CD4 T cells (nTreg), and a subset of NK cells.⁵⁹ Recent thymic CD4 and CD8 T cell emigrants mature in the periphery, where, unless activated, they can remain as circulating naïve T cells for the lifespan of the organism. Following activation by antigen-presenting cells, T cells expand and differentiate into several possible subsets. For CD4 T cells, these include the major Th1, Th2, Th17, follicular helper (T_{fh}), induced Treg (iTreg) subsets, and the less well-defined Th9 and Th22 populations that promote or inhibit distinct immune response activities.⁶⁰⁻⁶²

B cells develop in the bone marrow, where, like T cells, they undergo defined maturation stages and selection of antigen receptors (see also Chapter 14). In addition, class-switch recombination and somatic hypermutation of the B cell receptor occurs during T cell-dependent humoral responses. The main B cell types in the periphery include the conventional (or B2) and B1 subsets, with B2 cells further divided into follicular and marginal zone subsets.

Other essential constituents of the adaptive immune system are the professional antigen-presenting cells including, in addition to B cells, conventional dendritic cells (cDCs) and macrophages. Several other cell populations also directly affect adaptive immunity and include the follicular DCs, stromal cells, thymic epithelial cells, and others, while cell types such as NK cells, NK T cells, mast cells, and basophils variously modify adaptive responses.

TOLERANCE MECHANISMS

Increasing insights into mechanisms of self-nonsel self discrimination have emerged over the past 6 decades in parallel with growing knowledge of the immune system. More than 50 years ago, Burnet and Medawar advanced the critical concept that tolerance was imposed by clonal deletion of self-reactive lymphocytes during early development (i.e., central tolerance).^{63,64} Later, with the discovery that mature B cells undergo somatic hypermutation in the periphery, it was hypothesized by Bretscher and Cohn that the production of autoantibodies might be impeded by the need for both B and T cell compartments to breach tolerance.⁶⁵ In 1975, while studying allogeneic responses, Lafferty and Cunningham posited that activation of T cells involved the passing of a second signal that need not be antigen-related, thereby implicating costimulation from antigen-presenting cells as a critical factor in lymphocyte activation.⁶⁶ In 1987, the nature of the costimulation, or two-signal, requirement was further defined when Jenkins and Schwartz showed that engagement of antigen receptor alone without a second signal resulted in functional inactivation of T cells.⁶⁷ A novel mechanism for self-nonsel self discrimination that incorporated the innate immune system was then advanced by Janeway in 1989 when he hypothesized that antigen-presenting cells critical for T cell activation remain

quiescent unless activated by the engagement of PRRs by microbial products.⁶⁸ This concept was further extended by Matzinger in 1994 to a “danger model” that includes activation of the immune system by both foreign and endogenous factors associated with tissue stress and damage.⁶⁹ These models have laid the foundation for the current, more complex, view of self-nonsel self discrimination in which tolerance is imposed by both innate and adaptive immune systems through layers of mechanisms occurring at various stages throughout lymphocyte development and activation (Table 20-4).

Clone-Specific Self-Nonsel Recognition

In contrast to innate immune cells, which are activated primarily by hardwired microbial PRRs, lymphocytes are unrestricted in specificity and therefore self-nonsel self discrimination must be implemented at the clonal level. To achieve this, T and B cells use several mechanisms that can be grouped into three general strategies. First, the type of response is controlled by developmental stage. For example, immature lymphocytes respond to strong antigen receptor stimulation by cell death, whereas a similar signal in mature cells leads to activation. Through this mechanism self-reactive clones are eliminated from the nascent lymphocyte repertoire before they can cause injury. Second, activation of mature lymphocytes requires—in addition to antigen receptor engagement—a second co-stimulatory signal that, if absent, results in anergy or cell death. For the most part, this requirement limits reactivity to self because co-stimulatory signals are largely provided by activated cells of the innate immune system. Third, lymphocytes are fine-tuned in various ways by a fairly extensive list of modulating factors, which is necessary for controlling self-reactive clones.⁷⁰⁻⁷² For example, defects affecting a broad range of surface receptors on lymphocytes, including those with pro-survival (IL-7R, BAFFR, IL-2R); proapoptotic (TNFRs, FasL, TRAIL); costimulatory (CD28, CD40, TLRs); differentiating (IL-12R, IL-4R, IFN γ R, IL-23R, retinoic acid R, transforming growth factor (TGF)- β R, SAP/SLAM family members, OX40, ICOS/ICOSL); inhibitory (Fc γ RIIb, CD22, CTLA4, PD-1); antigen receptor signal modulating (CD19, CD45); and activating (SAP/SLAM family members) activities have been shown to influence the development of autoimmunity.⁹ Collectively, these self-nonsel self recognition mechanisms provide the basic cellular means by which the innate and adaptive immune systems render T and B cell clonotypes tolerant to self-antigens and resistant to autoimmune disease.

Innate System and Tolerance

Given its vital role in initiating and modulating adaptive immune responses, it is not surprising that the innate immune system strongly influences both tolerance and autoimmunity. Indeed, although its contributions have yet to be fully explicated, several ways in which self-tolerance is influenced by the innate arm have been defined. First, as noted previously, activation of the innate immune system under normal circumstances typically requires engagement of microbial PRRs, which endows the immune system with a direct and simple way to distinguish foreign- from

Table 20-4 Multiple Tiers of Tolerance

Type	Cell Type	Site	Mechanism
Central Compartment			
Central tolerance	T cells	Thymus	Primarily deletion, anergy, possibly editing
	B cells	Bone marrow	Editing, anergy, deletion
Peripheral Compartment			
Immature B cell tolerance	Transitional 1 (T1) B cells	Periphery	Deletion, anergy upon activation
Peripheral anergy	T and B cells	Secondary lymphoid organs and peripheral tissue	Inadequate signal induces cell inactivation
Ignorance	T cells; maybe B cells	Peripheral and secondary lymphoid organs	Insufficient self-antigen or co-stimulation
Inaccessible self-antigen	T and B cells	Peripheral organs	Sequestration, crypticity
Regulation	T and B cells	Secondary lymphoid organs and site of inflammation	Suppression by regulatory cells via intercellular signals and cytokines
Clonal deletion following activation	T and B cells	Site of inflammation and secondary lymphoid organs	Apoptosis caused by a decline in survival factors
Cytokine deviation	T cells	Site of inflammation and secondary lymphoid organs	Differentiation toward less pathogenic Th subsets
Postsomatic hypermutation	B cells	Germinal center	Insufficient CD4 T cell help, deletion (via <i>Fas</i>)
Tissue resistance	B and T cells	Peripheral tissues	Inhibitory intercellular signals and cytokines
Innate Mechanisms			
PRR engagement required for activation	Innate cells	Site of inflammation	Simple mechanism for self-nonself discrimination
Suppression of adaptive immune responses	Immature and mature DCs	Site of inflammation and secondary lymphoid organs	Delivery of inhibitory signals and activation of Treg
Clearance of apoptotic cells	Complement, phagocytes	Peripheral tissues	Removal of potential proinflammatory material and self-antigens
Complement-mediated effects on adaptive responses	Lymphocytes, innate cells	Secondary lymphoid organs and peripheral tissue	Modulation of activation

self-antigens.⁷³ The importance of this mechanism is illustrated by the finding that overexpression of TLR7 by spontaneous gene duplication or transgenic approaches promotes systemic autoimmunity.³⁶ This occurs because certain PRRs, such as TLR7 and TLR9 that equally sense both foreign and self-nucleic acids, avoid significant exposure to endogenous nucleic acids by virtue of their location in subcellular compartments.⁷⁴ However, in the case of TLR7, overexpression makes it possible for normally substimulatory amounts of endogenous RNA to activate immune cells, thereby bypassing the usual requirement for microbial exposure. Second, some cells of the innate immune system actively suppress adaptive immune system activation under certain conditions. For example, immature and, under some circumstances, even mature dendritic cells have been shown to promote tolerance by inducing CD4 T regulatory (Treg) cells and other mechanisms.⁷⁵ Third, another critical function of the innate immune system is the rapid noninflammatory clearance of apoptotic cells.⁷⁶ Failure can result in an increased supply of self-antigenic material including nucleic acids, secondary necrosis, and release of proinflammatory factors, leading to systemic autoimmunity.⁷⁷ Accordingly, deficiencies in several key apoptotic cell clearance molecules are associated with autoimmunity including (1) the Tyro3-Axl-Mer receptors on phagocytes that bind through Gas6 or protein S, the exposed phosphatidylserine (PS) on apoptotic cells⁷⁸; (2) the milk fat globule-EGF factor 8 (MFG-E8) protein that bridges the $\alpha v \beta 3$ integrin

on phagocytes and PS on apoptotic cells^{79,80}; and (3) natural IgM or C1q that binds to and enhances clearance of apoptotic cells.⁸¹⁻⁸³ Fourth, several complement components have been directly implicated in autoimmunity. For example, SLE is associated with deficiencies of proximal components of the classical pathway including C1q, C4, and C2. The mechanism for this is not certain, but both defective clearance of apoptotic material/immune complexes and a shift in the activation threshold of lymphocytes have been suggested.⁸⁴ As another example, deficiency of CD55 (or decay-accelerating factor), a cell surface protein that restricts complement activation, is associated with enhanced T cell responses and exacerbation of neuroinflammation and lupus in animal models.^{85,86} Thus at many levels, the innate immune system plays a critical role in maintaining tolerance and controlling autoimmunity.

T Cell Tolerance

T cells are critical players in both achieving and fine-tuning tolerance to a high degree of specificity. Researchers have identified several mechanisms and divided them into three main areas: central tolerance wherein T cells first acquire their antigen receptor, peripheral tolerance wherein T cells encounter self-antigens not present in the thymus, and post-activation regulation wherein activated and expanded T cell clones are returned to their resting state. Central tolerance, as alluded to earlier, is imposed on T cells with

self-reactive specificities during thymocyte development by mechanisms using primarily deletion, to a lesser extent anergy, and possibly receptor editing of the TCR α -chain.^{87,88} This process, although highly effective, is not completely efficient, and T cells with autoreactivity, primarily those with intermediate to low affinity to self or recognizing self-antigens poorly expressed in the thymus, emigrate in significant numbers. This leakiness is probably necessary to generate a broad repertoire, but it then creates vulnerability to autoimmunity and necessitates peripheral tolerance mechanisms.

In the periphery, multiple mechanisms for avoiding auto-reactivity have been identified. Among these, a common explanation is that most tissue-associated self-antigens are not accessible to trigger a response, a situation that can be caused by low abundance, specific characteristics of the self-antigen, or location. This mechanism is supported experimentally by the finding that T cells expressing a transgenic TCR to certain tissue-specific antigens are not deleted or activated, nor do they cause autoimmune disease. Yet these so-called “ignorant” T cells are fully functional and respond to self-antigen when presented in a conventional context such as inflammation or tissue damage.^{18,89} For a few self-antigens such as those expressed in the anterior chamber of the eye, central nervous system, or other so-called immunologic privileged sites—as originally defined by their ability to accept allograft transplants—resistance to self-reactivity also partly arises from anatomic sequestration caused by limited access of blood-borne cells and the absence of conventional lymphatic drainage.⁹⁰ The latter is important because T cells are typically first activated in secondary lymphoid organs and subsequently migrate to target organs, where reactivation by local antigen-presenting cells and the production of proinflammatory factors leads to tissue damage.⁹¹ Anatomic sequestration alone, however, is not sufficient for tissues to support immunologic privilege and, as discussed later, such sites employ a host of additional local mechanisms.^{92,93}

Another peripheral mechanism is the aforementioned two-signal paradigm wherein T cell activation requires both TCR engagement and a co-stimulatory signal usually provided by CD28. Because the two ligands for CD28, CD80 and CD86, are primarily expressed at high levels on activated professional antigen-presenting cells, presentation of self-antigen by quiescent antigen-presenting cells would lead to tolerance. Indeed, immature DCs promote tolerance in this manner by constitutively presenting low doses of self-antigen on MHC, resulting in cell death or anergy of the corresponding T cells.⁹⁴

Peripheral tolerance of T cells is also maintained by active suppression via immunoregulatory cells of the immune system, among which CD4⁺ Tregs are the best characterized. They constitute a distinct $\alpha\beta$ T cell subset generated in the thymus (natural Treg, nTreg) or in the periphery from naïve or mature CD4⁺ T cells exposed to TGF- β (induced Treg, iTreg). Both are developmentally induced by the Foxp3 (forkhead boxP3) transcription factor. They typically express high levels of the IL-2 receptor component, IL-2R α (CD25), and require IL-2 for survival. Tregs participate in every adaptive immune response, are critical for maintaining the proper level of immune response, and are activated at the same time as conventional T cells. They

are thought to suppress the magnitude of the response by (1) initially downregulating DC function and then inhibiting T cell activation by competing for IL-2, (2) producing immunosuppressive cytokines such as TGF- β , IL-10, and IL-35, and (3) by cell-cell inhibitory interactions that lead to cell killing or the induction of negative signals.⁹⁵ These inhibitory actions suppress T cells that are in proximity to Treg cells regardless of their antigen specificity.⁹⁶ Researchers have described other T cells with regulatory activity in autoimmunity including Tr1, CD8 Treg, Qa-1/HLA-E-restricted CD8 T cells, and $\gamma\delta$ T cells, but they are less well characterized.⁹⁷⁻¹⁰¹

Tissues themselves also employ mechanisms that suppress self-reactivity and contribute to establishing immune privilege.^{92,102-104} These comprise three general categories. First, certain tissues are decorated with cell surface inhibitory molecules such as the proapoptotic FasL and TRAIL, lymphocyte inhibitory and Treg-promoting PD-L2, and complement regulatory proteins, CD55 and CD46, that can potentially eliminate or impede the activation of autoreactive T cells. Second, soluble inhibitors of inflammation and immune activation are secreted by particular tissues. Notably, in the aqueous humor of the eye, there is a broad spectrum of such factors that include TGF- β , α -melanocyte-stimulating hormone, vasointestinal peptide, calcitonin gene-related peptide, somatostatin, macrophage inhibitory factor, and complement inhibitors. Third, lymph node resident stromal cells have been shown to induce tolerance of CD8⁺ T cells recognizing peripheral tissue-restricted self-antigens.^{105,106} Thus, it has been proposed that stromal cells in lymph node and tissues may provide a means to eliminate T cells that bind to tissue-restricted antigens not expressed in the thymus. Fourth, the anterior chamber of the eye elicits a unique type of altered immune response through a complex multistep process termed *anterior chamber-associated immune deviation* (ACAID) that leads to a dampened and less tissue-destructive response.^{92,104,107} Although ACAID was long thought important for tolerance, it was recently argued that its primary function may be to modulate the immune response so that the eye can respond to infection without damaging its integrity.¹⁰⁸

Another possible peripheral mechanism is immune deviation wherein polarization away from a predisposing cytokine pattern, such as from a Th1 to a Th2 profile, suppresses the development of autoimmune disease.¹⁰⁹ Similarly, activation of NKT cells with α -GalCer, which induces IFN- γ production, is associated with dampening of the adaptive Th1 and Th17 effector responses and protection from experimental autoimmune uveitis.¹¹⁰ In these models, autoreactive T cells are activated but do not produce the proinflammatory factors necessary for tissue damage.

In addition to central and peripheral tolerance, the immune system must also avert autoimmunity by suppressing or eliminating T cells following their activation or expansion. This regulation is mediated by several processes, including upregulation of inhibitory receptors such as CTLA4, expression of proapoptotic receptors like Fas, and release of intracellular proapoptotic factors such as Bim. Deficiencies of such mediators that control the magnitude of T cell responses are associated with severe expansion of lymphocyte populations and with varying degrees of autoimmunity.

B Cell Tolerance

B cells are required not only for antibody production but also serve as potent antigen-presenting cells for T cells and follicular DCs, and can act in regulation as well.¹¹¹ Moreover, depletion of B cells with rituximab has shown promise even in autoimmune diseases considered to be mediated by T cells such as T1DM¹¹² and multiple sclerosis.¹¹³ Therefore, there is substantial interest in defining both mechanisms of B cell tolerance and the specific role of B cell tolerance in autoimmune disease.

Before discussing specific tolerance mechanisms, however, it should be emphasized that the fate of B cells after antigen receptor (BCR) cross-linking is highly dependent on developmental stage, context and strength of signal, and the nature of the antigen, probably more so than for T cells because B cells are subjected to less stringent selection during central tolerance. Several checkpoints considered important for controlling autoreactive B cells and for maintaining self-tolerance have been identified and include many central and peripheral mechanisms similar to those described for T cells, as well as a few additional ones.

Central tolerance of B cells takes place in the bone marrow during preB to immature B cell transition as they express rearranged immunoglobulin (Ig) genes on their surface.¹¹⁴ It appears that the dominant mechanism for B cells with high affinity to membrane-bound self-antigen is receptor editing (replacement of L-chain) and, to a lesser extent, deletion, while soluble self-antigens induce both receptor editing and anergy.^{115,116} Anergic B cells are detectable in the periphery as an IgD⁺IgM⁻ population¹¹⁷ or in mice as splenic transitional 3 (T3) B cells.¹¹⁸ They are short-lived at least in part because they downregulate the BAFF receptor, which is required for their survival, putting them at a competitive disadvantage with other immature B cells, and they are less able to enter B cell follicles.

In the periphery, the earliest tolerance checkpoint occurs at the transitional 1 (T1) B stage over a 2-day interval before maturation to T2 and later naïve B cell subsets.^{114,119-121} T1 B cells are the immediate bone marrow emigrant population, retain an immature phenotype, and are BAFF-dependent for survival. Importantly, they undergo apoptosis and not activation when stimulated, which results in deletion of B cells recognizing peripheral self-antigens not expressed in the bone marrow compartment. Thus, this mechanism, which is unique to B cells, represents in essence an extension of central tolerance to the periphery.

Other peripheral tolerance mechanisms are achieved through many of those described earlier for T cells but differ qualitatively due to distinct differentiation pathways and differences in antigen recognition by B cells and T cells (i.e., BCRs can bind to virtually all tertiary structures while TCRs are restricted to recognizing self-MHC/peptide complexes on host cell surfaces). Accordingly, B cells can be ignorant of their corresponding self-antigen because of insufficient quantity or access¹⁹ or can undergo anergy and ultimately cell death if there is engagement of the BCR without co-stimulation (i.e., two signals).¹²²

Another notable checkpoint occurs during T cell-dependent immune responses as B cells undergo affinity maturation in germinal centers (GCs) and acquire new specificities, which may include self-reactivity. Evidence

suggests that tolerance at this juncture is often defective in autoimmune diseases because most autoantibodies have acquired autoreactivity through somatic hypermutation and are class-switched,¹²³⁻¹²⁵ both indicative of GC maturation. Although recent studies have provided significant insights into GC processes involved in the selection of B cell clones with high affinity to foreign antigens, how tolerance of class-switched autoreactive B cells is achieved remains to be clarified. Nevertheless, the strongest evidence suggests (1) autoreactive B cells compete poorly for the cognate T cell help essential for GC B cell survival because the autoreactive BCR would bind less well to the original antigen, resulting in less internalization of antigen for processing and presentation to T cells¹²⁶⁻¹²⁸ and (2) B cells that acquire BCRs with high affinity to membrane antigens are deleted by a Fas-dependent mechanism.¹²⁹

THEORIES OF AUTOIMMUNITY

Development of autoimmune diseases is influenced by genetic and, to varying degrees, environmental, gender, and other factors, with current evidence supporting a model in which genetic predisposition is required (Figure 20-1). Therefore, theories of autoimmunity and loss of tolerance are closely intertwined with genetic influences. In addition, such theories must also explain how tolerance is breached when autoimmunity is induced in otherwise normal animals. Taking both these factors into account and applying a reductionist perspective, theories of autoimmune disease can be consolidated into two main mechanisms representing separate ends of a continuum—most diseases having some elements of both. On one end, loss of tolerance and the consequent autoimmune disease is caused by genetically imposed defects in central and/or peripheral tolerance mechanisms while, on the other end, autoimmunity arises from the conventional immune response to self-antigens for which tolerance is normally incompletely established (Table 20-5). In general, most systemic autoimmune diseases are caused by tolerance defects, whereas organ-specific diseases can be mediated by either mechanism.

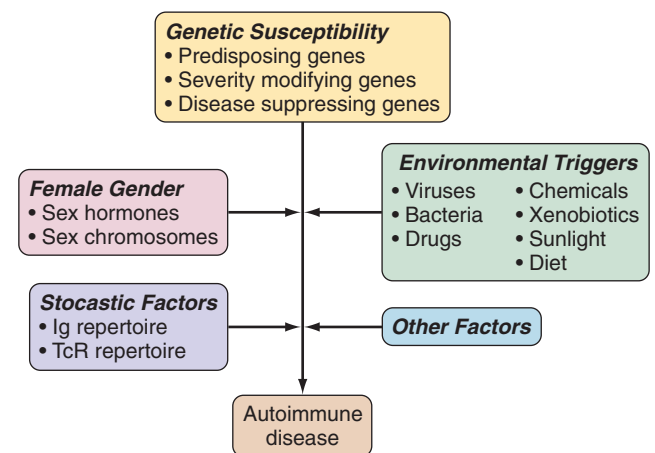

Figure 20-1 Etiology of autoimmune diseases. Autoimmune diseases are usually caused by the additive effects of autoimmunity-promoting environmental, gender, and other factors superimposed on significant underlying genetic predisposition.

Table 20-5 Mechanisms of Autoimmunity

Examples	Disease	Mechanism
Defective Tolerance		
Central Defects		
AIRE deficiency	APECED syndrome	Failure to delete autoreactive T cells because of reduced expression of peripheral antigens in thymus
ZAP-70 deficiency	Inflammatory erosive arthritis (mice)	Defective T cell activation and thymic selection
Peripheral Defects		
FAS/FASLG deficiency	Autoimmune lymphoproliferative syndrome (ALPS)	Defective apoptosis
Rc3h1 (M199R) mutation	Lupus (mice)	Increased ICOS on Tfh cells promotes their expansion
TREX1 (DNase III) deficiency	Aicardi-Goutières syndrome, chilblain lupus	Accumulation of intracellular DNA induces IFN- α production
FOXP3 deficiency	IPEX syndrome	Absence of Treg cells
PD-1 deficiency	Lupus, myocarditis (mice)	Defective peripheral tolerance of T cells
Activation of Nontolerant Lymphocytes		
Penetrating injury	Sympathetic ophthalmia	Release of self-antigen in an inflammatory milieu
Coxsackie B virus infection	T1DM (mice)	Infection-mediated release of self-antigen in an inflammatory milieu
Immunization with self-antigen and strong adjuvant	EAE (mice)	Activation of ignorant T cells
Citrullination of proteins	RA	Generation of neo self-antigens
Altered structure of collagen IV caused by sulfilimine bonds	Goodpasture's syndrome	Formation of conformational neo self-antigens
Cross-reactivity of group A streptococcal and cardiac antigens	Rheumatic fever	Molecular mimicry
Lymphopenia caused by disease associated IL-21 production	T1DM (NOD mice)	Lymphopenia-induced homeostatic proliferation

AIRE, autoimmune regulator; APECED, autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy; EAE, experimental autoimmune encephalomyelitis; FASLG, FAS ligand; FOXP3, forkhead box P3; ICOS, inducible T-cell co-stimulator; IFN- α , interferon- α ; IL-21, interleukin-21; IPEX, immune dysregulation, polyendocrinopathy, enteropathy X-linked; NOD, non-obese diabetic (mouse strain); PD-1, programmed cell death 1; RA, rheumatoid arthritis; T1DM, type 1 diabetes mellitus; TREX1, three prime repair exonuclease 1; ZAP-70, zeta-chain-associated protein kinase 70.

Defective Tolerance

Although one can infer that loss of tolerance underlies autoimmunity, the specific tolerance defects causing common autoimmune diseases have been difficult to delineate, presumably because of modest defects at multiple checkpoints. Nevertheless, studies of monogenic human autoimmune disease and animal models have identified a wide range of defects in the various layers of central and peripheral tolerance. Such defects are caused by diverse genetic abnormalities and are mediated by a variety of lymphoid and nonlymphoid cell types. A few representative examples follow.

Defects in central tolerance have long been suspected to cause autoimmunity because of its well-documented role in eliminating nascent self-reactive lymphocytes, but until recently solid evidence for this was lacking. A breakthrough came from the discovery that mutations in a transcription factor, AIRE (for autoimmune regulator), caused autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED), a rare inherited disease associated with T cell and autoantibody-mediated autoimmune destruction of multiple endocrine organs.^{130,131} AIRE-deficient mice developed a similar syndrome, which was caused by reduced expression of thousands of peripheral tissue genes in the thymic medullary epithelium and consequently failure to eliminate T cells specific for those gene products. Thus it appears that the main function of AIRE is to prevent

autoimmunity by deleting T cells recognizing peripheral tissue self-antigens.

Another example of altered thymic selection leading to autoimmunity, but in this instance caused by a defect in T cells, is the aforementioned SKG arthritis model. Here, a function-impairing mutation in the C-terminal SH2 domain of ZAP-70, a Syk family tyrosine kinase activated by the T cell receptor complex ζ -chain, reduces TCR signaling, leading to defective conventional T cell and nTreg development in the thymus, and presumably enhanced positive selection of autoreactive T cells.¹³² Interestingly, using several ZAP-70 mutants, researchers showed that slight differences in ZAP-70-mediated signaling strength affected arthritis susceptibility.^{132,133}

For B cells, major defects in central tolerance leading to autoimmunity have been more difficult to prove and no AIRE-like equivalent has been discovered. Nevertheless, defective central tolerance of B cells in autoimmunity has been suggested by the finding of a higher frequency of naïve mature B cells with self-reactivity in patients with SLE and RA.¹³⁴⁻¹³⁶

Moving to the periphery, an example of defective peripheral tolerance promoting autoimmunity is FAS deficiency.¹³⁷ FAS is a proapoptotic surface receptor that plays a critical role in maintaining immunologic homeostasis by eliminating undesired cells. Defects in FAS cause autoimmune lymphoproliferative syndrome (ALPS), also called Canale-Smith syndrome, and in mice, lymphoproliferative (*lpr*) disease,

both of which exhibit massive enlargement of secondary lymphoid organs—caused mainly by the accumulation of a normally rare so-called “double negative” subset of T cells that lack both CD4 and CD8 co-receptors—and a variety of autoimmune manifestations. *Lpr* mice are defective in eliminating B cells that acquire self-reactivity in the periphery, a process that typically occurs in the GC during somatic hypermutation.¹²⁹ Similar abnormalities have been described in humans and mice with defects in the ligand for FAS, FASLG.¹³⁸

Peripheral tolerance is also breached by overexpression of the costimulatory molecule ICOS on T follicular helper (T_{fh}) cells in *Sanroque* mice. These mice have a point mutation in the *Rc3h1* gene, a RING-type ubiquitin ligase, that impairs its ability to degrade ICOS mRNA.¹³⁹ Increased expression of ICOS promotes the expansion of T_{fh} cells and germinal centers, production of IL-21, and autoimmunity.¹⁴⁰

An example of a lymphocyte-extrinsic cause for loss of tolerance and autoimmunity is deficiency in the 3' repair exonuclease 1 (TREX1, DNase III). Loss-of-function mutations in TREX1 have been implicated in the Aicardi-Goutières syndrome, a rare progressive encephalopathy associated with elevated IFN- α levels in cerebrospinal fluid, and chilblain lupus, a rare form of SLE characterized by painful, bluish-red inflammatory skin lesions typically affecting areas exposed to cold.^{141,142} Autoimmunity is thought to be caused by the intracellular accumulation of ssDNA derived from endogenous retroelements normally degraded by TREX1, resulting in the activation of intracellular DNA sensors and consequent over production of IFN- α .^{143,144} The importance of DNA disposal in lupus has been further illustrated by the association of DNase I deficiency with development of lupus in humans and mice.^{145,146}

Defective regulation can also result in loss of tolerance and autoimmune disease as illustrated by the absence of Tregs.^{147,148} In humans, monogenic deficiency of the *FOXP3* gene, which is required for Treg development, is associated with the IPEX (immune dysregulation, polyendocrinopathy, enteropathy X-linked) syndrome, a severe systemic autoimmune disease associated with diarrhea, eczematous dermatitis, and endocrinopathy, usually fatal within the first year. T1DM, autoimmune cytopenias, and nephritis are among other less common autoimmune manifestations of this syndrome. Similar findings are observed in *scurfy* mice that have a spontaneous function-impairing mutation of *Foxp3*.

Autoimmunity Caused by Activation of Intolerant or Partially Tolerant T Cells

Another theory is that autoimmunity develops through the conventional activation of self-reactive T cells that have not been deleted in the thymus and remain oblivious to the corresponding self-antigen after emigration. Such ignorant T cells, commonly found in the periphery of both normal humans and animals, can be activated by antigen presented by professional antigen-presenting cells in the context of an innate inflammatory milieu. Once activated, T cells can gain access to virtually all tissues and, when activated again locally, can elaborate proinflammatory factors causing tissue damage.⁹¹ Breach of tolerance by this mechanism is most

often associated with organ-specific diseases, presumably because tissue-specific antigens are less likely to be expressed in the thymus. This theory is supported by the finding that type 1 diabetes is prevented in BB rats and NOD mice by intrathymic transplantation of pancreatic islets^{149,150} or inhibited in NOD mice by intrathymic administration of GAD, a major β -islet autoantigen in this model.^{151,152} Similarly, EAE can be prevented by intrathymic administration of either the immunizing antigen, myelin basic protein, or its major encephalitogenic epitope,¹⁵³ and autoantibody production can be delayed in lupus-prone mice following intrathymic injections of polynucleosomes.¹⁵⁴ Taken together, these data support the concept that autoimmunity can be caused by the activation of lymphocytes to self-antigens for which there was incomplete central tolerance. This is similar to the mechanism underlying the APECED syndrome caused by AIRE deficiency, but in this instance central tolerance is not known to be defective.

Breach of tolerance by ignorant lymphocytes has been shown to depend on many factors including the (1) nature of the self-antigen, (2) extent of exposure to antigen, (3) antigen receptor affinity, (4) frequency of autoreactive lymphocytes, (5) types and levels of co-stimulatory molecule expression, (6) cytokine and chemokine profiles, and (7) presence of inflammation.^{18,155-161} It should also be emphasized that despite the presence of lymphocytes that recognize self-antigen, peripheral tolerance mechanisms, under normal conditions, are difficult to overcome. Consequently, although the experimental autoimmune models are highly reproducible, they require supraphysiologic amounts of self-antigen, strong adjuvant, specific MHC haplotypes, and a susceptible background to break tolerance. Nonetheless, based on largely experimental evidence, researchers have identified a wide range of mechanisms that can lead to loss of tolerance, activation of autoreactive lymphocytes, and autoimmune disease. Although their specific contributions to human diseases are not yet known, they provide a framework for understanding how autoimmunity can develop.

Similar to immune responses in general, key factors for the initiation of autoimmunity are innate inflammatory and co-stimulatory factors that promote the initial activation and expansion of naïve autoreactive lymphocytes. This is thought to contribute to the autoimmune response by the release of self-antigens following cell damage or death, increased MHC/peptide expression, upregulation of co-stimulatory factors, and activation of professional antigen-presenting cells.^{156,157,162} Indeed, moderate to severe tissue necrosis is often associated with some evidence of autoreactivity, although this rarely progresses to autoimmune disease.^{163,164} In autoimmune diseases, chronic cell and tissue injury and the continual release of self-antigens under conditions favorable for antigen presentation and co-stimulation promotes epitope spreading and the activation of an expanding repertoire of lymphocytes recognizing autoantigens beyond the initiating one.^{165,166} This process is thought to account at least in part for the usual progressive course of autoimmunity. Overall, these and other findings support the theory that under certain conditions such as infection or trauma, self-antigens are released, which in the presence of inflammatory factors and an activated innate immune system, can lead to triggering and expansion of

self-antigen-recognizing lymphocytes and autoimmune disease.

In addition to the release of sequestered self-antigens, there are several other ways in which the initial activation of nontolerant lymphocytes has been postulated to occur. Some investigators have suggested the initial response may be directed toward certain cryptic determinants^{167,168} based on “crypticity,” the hierarchy of dominant and cryptic epitopes within a protein caused by differences in binding affinity to the MHC, protein processing, type of antigen-presenting cells, and the overall repertoire of epitope-specific T cells.¹⁶⁶ It was therefore posited that during thymic selection, T cells engaging the few dominant epitopes are eliminated, whereas those recognizing the less antigenic, but more abundant, cryptic epitopes are spared. These T cells then emigrate to the periphery, where they can be activated by the corresponding cryptic epitope under certain conditions.

Another mechanism by which self-antigens can activate nontolerant lymphocytes is through the production of neo self-antigens following post translational or chemical modifications. A prominent example of this is the formation of citrullinated proteins caused by the deimination of arginine residues by peptidylarginine deaminase (PADI) enzymes. Several citrullinated proteins are not only major targets of autoantibodies in a subset of RA but are thought to play a significant role in disease pathogenesis.¹⁶⁹⁻¹⁷¹ Deficiency of L-isoadipate O-methyltransferase (PMT), which catalyzes the repair of isoAsp proteins formed by the spontaneous conversion of aspartic acid to its isoaspartyl derivative, has also been shown to result in an accumulation of isoAsp proteins and the development of lupus in a mouse model.¹⁷² Furthermore, in the PL/J model of EAE, acetylation of the encephalitogenic Ac1-11 peptide of MBP is required for T cell activation even though unmodified peptide binds to MHC.¹⁷³ These and other studies suggest that protein modifications can generate new and/or cryptic epitopes either directly by creating new structures such as citrulline or indirectly by altering MHC binding or modifying sites of peptide processing.¹⁷⁴

Neo self-antigens can also arise from changes in overall structure. An example of this is the formation of immunogenic immune complexes from nonantigenic soluble monomeric IgG, which can induce rheumatoid factors, antibodies to the Fc portion of complexed IgG.^{175,176} Likewise in Goodpasture's disease, a configuration change in type IV collagen due to sulfilimine bonds produces a neotarget for pathogenic autoantibodies, a mechanism coined *conformeropathy*.¹⁷⁷

Another potential mechanism for triggering autoimmunity in susceptible individuals is lymphopenia-induced homeostatic expansion of T cells.^{178,179} Expansion occurs because of greater availability of survival-promoting cytokines (IL-7, IL-15), which, when combined with low-affinity engagement of the TCR to self-peptide/MHC, induces low-grade proliferation without full activation. It was therefore hypothesized that the requirement for self-reactivity could result in the preferential expansion of autoreactive T cells and consequently autoimmunity.¹⁷⁸ The presence of lymphopenia in certain autoimmune diseases such as SLE and RA, autoimmune manifestations in some primary immunodeficiencies with lymphopenia, and several experimental autoimmune models support this.

In addition to self-antigens, foreign antigens with sufficient sequence or structural similarity can cross-activate nontolerant T (and B) lymphocytes, a mechanism termed *molecular mimicry*.¹⁸⁰ For T cells, several findings support this possibility: (1) cross-reactivity requires only short peptide lengths of 8 to 15 amino acids; (2) T cell recognition is highly degenerate depending on only a few key amino acid residues, and it is possible to have mimotopes with no identical amino acids at any position^{181,182}; (3) it is estimated that a single T cell can react with 10^4 to more than 10^8 different peptides¹⁸³; (4) MBP-specific T cells cloned from MS patients can be stimulated by diverse microbial peptides^{184,185}; and (5) infection with a modified Theiler's virus expressing a foreign cross-reactive peptide (*Haemophilus influenzae* protease IV protein that shares only 6 of 13 amino acids) induced T cells against a myelin protein, proteolipid protein (PLP), resulting in autoimmune CNS disease.¹⁸⁶ To date, however, there is no compelling evidence connecting a specific microbial T cell mimotope to any autoimmune disease.^{187,188}

In contrast, there is fairly good evidence for molecular mimicry affecting self-reactive B cells for a few autoimmune diseases. The best examples include cross-reactivity of (1) bacterial adhesin FimH with LAMP-2 (lysosomal membrane-2) in ANCA-positive pauci-immune focal necrotizing glomerulonephritis¹⁸⁹; (2) group A streptococcal carbohydrate epitope, N-acetyl glucosamine, and M protein with cardiac myosin in rheumatic fever¹⁹⁰; and (3) *Campylobacter jejuni* lipo-oligosaccharide with ganglioside GM1 on peripheral nerves in the acute motor axonal neuropathy subtype of Guillain-Barré syndrome because of an identical determinant, [Gal β 1-3 GalNAc β 1-4 (NeuAc α 2-3) Gal β].^{191,192} Overall, however, although molecular mimicry is an attractive hypothesis, supportive evidence for most autoimmune diseases is lacking. Whether this is because of multiple mimotopes from diverse sources or to perhaps the considerable plasticity of the T cell receptor remains an open question.

IMMUNOLOGIC MECHANISMS OF TISSUE INFLAMMATION AND DYSFUNCTION

The same effector mechanisms used by the immune system to neutralize pathogens are exploited in autoimmunity to inflict a wide range of deleterious effects on self-molecules, cells, and tissues. These have been broadly grouped into hypersensitivity types II to IV, which respectively encompass antibody-, immune complex-, and T cell-mediated processes (see Table 20-2).

In Type II reactions, pathologic autoantibodies bind to self-antigens primarily located on cell surfaces or in tissues and mediate autoimmune disease by three general mechanisms: (1) altering the function of the target antigen, (2) promoting cell injury or death, and (3) inducing inflammation. Blocking or enhancement of self-molecule function represents a special kind of type II hypersensitivity response in which autoantibodies alone are sufficient to effect autoimmune manifestations. Examples include the agonist anti-TSH receptor antibodies in Graves' disease that stimulate

thyrocyte growth and production of thyroid hormone, the antiacetylcholine receptor antibodies that block neuromuscular transmission in myasthenia gravis, and anti- β 2-glycoprotein I antibodies in antiphospholipid syndrome that alter the regulation of anticoagulant activity.¹⁹³

Direct cell injury or death is mediated by the binding of IgM or IgG to surface antigens leading to cell lysis directly by complement activation or to phagocytosis via interaction of deposited C3 fragments with CR1 and CR3 receptors. Bound IgG also promotes phagocytosis through its interaction with Fc receptors. Examples include autoimmune hemolytic anemia, idiopathic thrombocytopenia, and autoimmune neutropenia.

Finally, antibodies bound to tissue antigens promote inflammation by activating complement, which generates the chemoattractant C5a and leukocyte-activating C3 fragments, and by Fc γ R binding, which activates immigrating leukocytes such as neutrophils and macrophages, as well as tissue resident mast cells and basophils. These cells produce proinflammatory factors that further expand the inflammatory response by recruiting and then activating additional circulating leukocytes.

Abnormal deposition of immune complexes of IgG antibody and soluble antigen in tissues cause type III responses. Such complexes, which also contain bound C3 complement fragments, are normally removed from the circulation by complement receptors on RBCs and by complement receptors and Fc γ Rs on mononuclear phagocytes and platelets. However, this clearance can be overwhelmed under certain conditions such as overabundant production or immune complexes composed of excess antigen wherein less antibody coverage reduces both complement deposition and aggregation of Fc regions, leading to less efficient clearance. Once deposited in tissues, immune complexes initiate, through complement activation and Fc γ R binding, the same inflammatory cascades as type II responses. SLE and RA are autoimmune diseases mediated by this mechanism.

Type IV hypersensitivity encompasses cell and tissue injury mediated by activated T cells through their cytolytic activity in the case of CD8 T cells or the production of proinflammatory factors primarily by the CD4 subset. Apart from direct evidence for this mechanism in animal models using approaches not feasible in human studies, indirect evidence supporting this mechanism includes a higher frequency of autoreactive T cells with effector function in patients with autoimmune diseases, immunopathologic findings similar to T cell-mediated autoimmune models, and inhibition with T cell-blocking agents such as cyclosporin A.¹⁹⁴ T1DM and MS are examples of type IV reactions.

It should be mentioned, however, that the mechanism for some diseases is not always readily apparent. In RA, for example, the mechanism responsible for injury or dysfunction probably involves more than one hypersensitivity type,^{195,196} whereas in others such as SLE, different clinical manifestations are mediated by different mechanisms (e.g., antineuronal antibody-mediated CNS pathology is a type II process, whereas glomerulonephritis is type III).¹⁹⁷⁻²⁰⁰ Finally, for some diseases such as dermatomyositis and systemic sclerosis, the type of mechanism mediating tissue injury remains to be defined.

PATHOPHYSIOLOGY OF AUTOIMMUNE RHEUMATIC DISEASES

Although the general principles underlying loss of tolerance and autoimmunity provide a useful conceptual foundation, the actual pathophysiologies—suggested by the few better-defined autoimmune diseases—are likely to also employ specific and unique mechanisms. Two notable examples of this are the pathophysiology of antinuclear antibody production in SLE and arthritis in RA. Brief discussions in the context of their broader significance to autoimmune diseases follow (see also Chapters 69 and 79).

Recent findings suggest a model of SLE pathophysiology that provides a mechanism for why antinuclear antibodies are virtually always present in lupus despite substantial genetic and clinical heterogeneity.³⁶ First, autoreactive B cells activate when self-reactive BCRs bind to nucleosomes or RNPs and internalize them into the endolysosome compartment, where the released nucleic acids engage TLR7 and TLR9 and provide a second signal. Such activated B cells act as potent antigen-presenting cells for T lymphocytes, and following class-switch recombination they produce IgG autoantibodies. Next, immune complexes formed by the binding of these autoantibodies to nucleic acid-containing material activate pDCs and DCs following their internalization via Fc γ RIIA (Fc γ RIII in mice) and then engagement of TLRs by nucleic acids. Elaboration of lupus-promoting cytokines such as type I IFN and BAFF by pDCs and DCs, as well as enhanced antigen presentation, are thought to further drive loss of tolerance, activation of autoreactive B cells, and autoantibody production, thereby resulting in an amplification loop. Thus in lupus-susceptible individuals, confinement of nucleic acid-binding TLRs to endolysosomes is not enough of a barrier to block their activation by normally innocuous amounts of self-nucleic acids. This mechanism provides an explanation for the high prevalence of autoantibodies in SLE that either bind to nucleic acid or nucleic acid-complexed self-antigens such as DNA, nucleosomes, RNP, and myeloperoxidase (ANCA) or that exhibit cross-reactivity to such antibodies. Importantly, this also raises the possibility that other autoimmune diseases might also be mediated by specific PRRs.

The pathophysiology of RA also involves common and specific pathways that together promote inflammatory synovitis in roughly two phases,^{54,196,201,202} which has been best described for the HLA-DR1*401 (DR4) anti cyclic citrullinated peptide (CCP)⁺ subset of RA patients with greater disease severity. The initial phase is postulated to involve the activation of T cells and B cells and the production of autoantibodies, including RF and anti-CCP. Targets for anti-CCP include citrullinated fibrinogen, vimentin, and α -enolase, and these antibodies are thought to play a major role in disease pathogenesis, although the mechanism remains controversial. The specific triggers of the anti-CCP response are also not known, although it is postulated that release of peptidylarginine deaminase from apoptosing granulocytes and monocytes may be a contributing factor. The resulting immune complexes and activated T cells lead to stimulation of macrophages, synovial fibroblasts, endothelial cells, mast cells, and osteoclasts, and the eventual production of proinflammatory factors such as TNF, IL-1, IFN- γ , chemokines, matrix metalloproteinases,

osteopontin, and many others that contribute to synovitis, pannus formation, bone erosion, and cartilage destruction. This later inflammatory and tissue damaging phase is largely mediated by activated fibroblast-like synoviocytes, which produce a wide array of proinflammatory mediators that promote recruitment and activation of circulating and resident immune cells. It has also been suggested that the spread of arthritis to unaffected joints could, in fact, be mediated by transmigration of these activated fibroblast-like synovial cells.²⁰³ The pathophysiology of RA provides an additional example of the collaboration of the innate and adaptive arms of the immune system in autoimmune disease but also has two unique features; first, the major autoantigen, citrullinated protein, is a neoantigen specific for this disease, and second, tissue damage is ultimately mediated by fibroblast-like synoviocytes.

GENETICS OF AUTOIMMUNE DISEASES

Over the past few years, greater insight into the genetic landscape responsible for autoimmune disease susceptibility has come from both human and animal studies (see also Chapter 21). This progress was greatly facilitated by the availability of genomic sequences, improved definition of genetic variations and haplotypes among human populations, consortia with collections of patients and controls in the thousands, and numerous major technical and analytical advances.^{204,205} In particular, genetic studies have progressed from testing a few specific candidate polymorphisms to genome-wide family analyses of hundreds of cases, and even larger scale genome-wide association studies (GWAS) involving thousands,^{206,207} making it possible to capture common disease-predisposing variants with modest effects. Combined, these approaches have identified more than 30 candidate genes in SLE and RA, more than 10 in systemic sclerosis, and a few in Kawasaki's and Behçet's diseases²⁰⁸⁻²¹⁴ (see www.genome.gov/gwastudies for additional information). These candidates span the gamut of innate and adaptive immune systems but also include some loci with genes of unknown immunologic function. For example, in SLE, probably the best defined at the genetic level of any rheumatic disease, there are candidate genes involved in antigen presentation (HLA-DR3); B and T cell receptor signaling (*PTPN22*, *BANK1*, *BLK*), CD4 T helper cell regulation (*OX40L* or *TNFSF4*); T cell-mediated regulation (*PDCD1*); cytokine signaling (*STAT4*); interferon and TLR7/9 signaling (*IRF5*, *TNFAIP3*, *IRAK1*, *IRF7*, *TYK2*); Fc receptor function, one of which has been implicated in the transport of nucleic acid-containing immune complexes to TLR7/9-containing endosomes (*FCGR2A*); neutrophil function (*ITGAM*); clearance of self-antigens (*CIQ*, *C2*, *C4*); clearance of intracytoplasmic DNA (*TREX1*); and also several loci containing genes with no known connection to the immune system or lupus. Together these provide clues to specific pathways involved in SLE, which indeed has dovetailed well with more extensive genetic studies in mice encompassing more than 120 genes.⁹

From GWAS and other studies including those in animal models, several general conclusions can be made about genetic susceptibility in the more common autoimmune diseases. First, autoimmune diseases are associated with a large number of susceptibility genes shown to impact a wide

range of immunologic, cellular, and end-organ functions in ways that enhance, modify, or even suppress relevant pathophysiological processes.

Second, there is considerable genetic heterogeneity at both the individual and population levels regardless of whether the phenotype is relatively uniform as in RA or diverse as in SLE. Furthermore, although there are a large number of predisposing genes, having only a subset of these genes is sufficient for disease development. To what extent this heterogeneity is due to defects in a few common pathways or to numerous unique pathways remains unclear.

Third, the vast majority of candidate genes or loci have only modest effect sizes with most odds ratios less than 1.5, although in some diseases, notably SLE, a few rare variants (e.g., *CIQ* deficiency associated with > 90% incidence of SLE and *TREX1* mutations leading to chilblain lupus) have been identified that are highly penetrant. Another salient finding derived from GWAS analyses is that for most autoimmune diseases, HLA alleles consistently have the highest or among the highest effect sizes. This accords well with the central role of antigen presentation and T cells in directing the adaptive immune response to specific antigens. Overall, however, for most candidate variations, defining the mechanism and proving a role in autoimmune disease will be hampered by their low effect sizes.

Fourth, some of the variant genes and loci are shared among autoimmune diseases, suggesting common underlying mechanisms.²¹⁵ Noteworthy examples are the association of *PTPN22* with a wide range of autoimmune diseases including T1DM, RA, SLE, JIA, Graves' disease, systemic sclerosis, myasthenia gravis, generalized vitiligo, and granulomatosis with polyangiitis (formerly Wegener's granulomatosis), but not multiple sclerosis²¹⁶ and *STAT4* with RA, SLE, systemic sclerosis, and Sjögren's syndrome.^{217,218} This supports a role for genetic factors in the known occurrence of multiple different autoimmune diseases in some families.

Fifth, common single-nucleotide polymorphism (SNP)-defined variants account for only a portion of overall heritability in autoimmune diseases (i.e., ~20% to 60%)^{204,205,219} of which the HLA region typically accounts for a substantial part. Several reasons for the missing heritability have been suggested: (1) failed detection because of inadequate SNP coverage or the presence of disease-promoting non-SNP genomic variations such as copy number variants, (2) a large number of common variants with modest to marginal effects (odds ratio < 1.1 to 1.2) that are undetectable despite large study sizes given that the statistical power is reduced by both smaller effect size and lower variant frequency in the population, and (3) uncommon variants (1% to 5%) or rare disease-associated risk alleles (<1% frequency). Any of these possibilities will present significant challenges to further defining genetic susceptibility. It should also be noted that most common SNP variants associated with diseases do not affect coding regions, making it difficult to determine if the SNP variant is the actual change associated with disease and to decipher its effects on gene function and autoimmunity.

Finally, information gleaned from genetic studies to date has not been useful for identifying individuals at risk, and it is thought that this will remain so because of the small effect sizes and relatively high frequency of known risk

alleles, combined with incomplete coverage of heritability.²⁰⁵ Nevertheless, these data have helped define disease-relevant pathways and within that context may lead to the identification of potential therapeutic targets.

GENDER AND AUTOIMMUNITY

A significant female gender bias in autoimmunity was identified early on and was considered an important clue to disease pathogenesis.²²⁰ The strength of this predilection, however, varies among autoimmune disorders with female prevalence in the 80% to 95% range for thyroiditis, SLE, Sjögren's syndrome, and antiphospholipid syndrome, in the 60% to 75% range for RA, scleroderma, myasthenia gravis, and MS, but close to 50% for T1DM and autoimmune myocarditis.²²¹ Why some autoimmune diseases are affected more by gender than others is not known, but the lack of common or distinguishing characteristics in those diseases with higher female predominance suggests the possibility of multiple mechanisms.

Indeed, to differing extents, depending on the disease, both sex hormones and sex chromosomes have been implicated in this dichotomy. In addition, fetal-maternal chimerism has been suggested as another factor, but this remains controversial.²²² In terms of sex hormones, there is substantial evidence from *in vitro*, animal, and clinical studies to support a role for both female and male sex steroids in modifying the incidence and severity of autoimmunity. For example, in SLE, both estrogens and prolactin have been shown to exacerbate disease. In animal studies, they promote loss of tolerance and expansion of B cell populations, which, for estrogens, was also shown to be associated with enhanced survival and greater expression of Bcl-2.²²³ Importantly, studies of lupus-prone mice involving combinations of castration and hormone replacement convincingly demonstrated a disease-promoting effect of female hormones on spontaneous systemic autoimmunity.²²⁴

Evidence also supports a role for sex chromosomes in autoimmune disease susceptibility. Individuals with Klinefelter's syndrome (XXY) have a higher than expected incidence of SLE but under-representation in Turner's syndrome (XO).^{225,226} Furthermore, using genetic and gonad manipulation in mice that allowed direct comparison of the effects of one or two X chromosomes on autoimmunity, susceptibility to both EAE in SJL mice, and TMPD-induced lupus was shown to be more severe in mice with XX.^{227,228} Thus it appears that both hormonal and to some extent chromosomal influences play roles in female predilection to autoimmunity.

MICROBIAL AND OTHER ENVIRONMENTAL TRIGGERS

Considerable evidence indicates that environmental factors can exert varying degrees of influence on the development of autoimmune diseases. A clear causal effect has been documented for a few disorders, while the low concordance rate (20% to 50%) among monozygotic twins in common autoimmune diseases support the presence of a significant environmental component. Nevertheless, the specific environmental factors and the extent to which they contribute to disease induction and exacerbation remain largely

unknown for the majority of autoimmune disorders. The reasons for this are likely manifold and, depending on the disease, may include unsuspected or unknown environmental culprits, multiple independent factors, additive factors contributing to cumulatively small portions of the overall environmental effect, a highly variable or prolonged interval between exposure and disease onset, and a low incidence of autoimmune disease following exposure. Moreover, another general impediment is the difficulty of proving causation with epidemiologic data. Because of these difficulties animal studies have been invaluable in allowing controlled experimentation, and much of what we understand mechanistically has come about through this approach.

Despite these limitations, a broad range of environmental factors have been implicated, albeit with varying levels of confidence.²²⁹ Notably, the most prominent are infection and exposure to microbial products, which epidemiologic and animal models suggest can either enhance or inhibit autoimmunity depending on the type of exposure and disease.^{230,231} Several mechanisms by which microbes are postulated to induce or exacerbate autoimmunity include (1) molecular mimicry,¹⁹⁰ (2) bystander activation of autoreactive T cells by pathogen-activated antigen-presenting cells,²³² (3) inflammation of the target tissue and the release of immunologically hidden self-antigens,²³³ and (4) the production of disease-promoting cytokines such as IFN- α .³⁶ Inhibition of autoimmune diseases by pathogens was initially suggested by epidemiologic evidence in T1DM and multiple sclerosis consistent with the "hygiene hypothesis" (i.e., a lower incidence of infection is responsible for an increasing incidence of allergic disease in Western countries).²³⁴ This concept has since been supported by additional epidemiologic and experimental data, although the microbial pathogens, type of exposure, and mechanisms remain uncertain. A recent study, however, of T1DM-prone NOD mice, which get worse in clean conditions and better with exposure to microbial products, showed that alterations in gut microbiota, which can interact with and modulate the host immune and inflammatory apparatus, could account for a significant portion of the environmental effects.²³⁵ Many of these mechanisms do not require specific pathogens but can be mediated by a wide spectrum of organisms. Finally, there are animal models that develop autoimmune disease under germ-free conditions, thereby excluding the requirement for microbial environment or infection. In this case, one would infer that the trigger is provided by self, most likely cell damage-derived products. Examples include type 1 diabetes in NOD mice and BB rats, APECED in AIRE-deficient mice, IPEX in Foxp3 deficiency, and lupus in MRL-lpr mice.²³⁶⁻²⁴⁰ Interestingly, however, in MRL-lpr mice the addition of a filtered diet containing less PAMPs reduces disease severity. This suggests that microbial products at least partially affect disease susceptibility in this model and points to the difficulty of completely excluding a role for microbial organisms.

In terms of the other nonmicrobial environmental factors, some of the general types include (1) drugs such as procainamide, gold salts, and interferons that typically cause mild autoimmunity that resolves after discontinuation; (2) trauma, of which sympathetic ophthalmia caused by penetrating injury to the globe is an example, and (3) diverse environmental agents such as adulterated oil (caused

toxic oil syndrome), ultraviolet radiation (exacerbates systemic autoimmunity), iodine (autoimmune thyroiditis), silica (RA, SLE, systemic sclerosis), and tobacco smoke (anti-CCP⁺ HLA-DR4⁺ RA).^{171,229}

CONCLUSION

Since 1904, when Donath and Landsteiner reported the first evidence of self-reactivity in paroxysmal hemoglobinuria,²⁴¹ the field of autoimmunity has progressed tremendously at both the clinical and basic science levels. Notably, recent progress has made it possible to begin to dissect the interrelationships between genetic susceptibility and pathophysiology, and indeed several novel pathways linking etiology with immunopathology have already been identified. Recent studies have also been instrumental in documenting the central role of innate responses in the development of autoimmune adaptive immune responses. Importantly, they suggest that PRR-mediated innate immune responses might be a general requirement for the initiation of autoimmunity and furthermore that the type of adaptive autoimmune response and type of autoimmune disease may be largely determined by the nature of the innate response. Also, of importance to patient care, has been the successful bench-to-bedside translation approach that has brought therapeutic targeting of specific immune-related molecules to the clinic. Despite these substantial areas of progress, however, many facets of autoimmunity are still incompletely understood and patient care thus remains suboptimal. For instance in the area of therapy, the highly sought objective of specifically eliminating autoreactive, but not foreign, antigen-recognizing lymphocytes has remained elusive despite considerable effort^{242,243} and current, more broadly immunosuppressing therapies are only partially effective and are associated with infection and cancer risks. Accordingly, there continues to be a critical need to investigate the basic processes involved in autoimmune diseases and to develop new and more effective ways to manage afflicted individuals.

With this in mind, there are several areas of research that are poised to address some of the current deficiencies. At the bench it can be anticipated that the pathophysiology of at least the common autoimmune diseases will be defined in increasing detail, and the critical corresponding cell types and molecular components identified. In animal studies, existing technology is at the point where all genes essential for the development of a particular autoimmune disease model can be identified. Genetic studies in both human and animal models should continue to help focus clinical efforts on relevant immune and cellular pathways, and new technologies are likely to make it possible to identify rare disease-affecting genetic variants. In the clinic, major benefits are likely to be derived from new biomarkers, new therapeutics, predictive risk factors both genetic and environmental, and the transformation to individualized care approaches. In general, scientific advances in genome sequencing, application of a systems biologic approach, and instrumentation are also likely to have positive impacts. Thus, the future should continue to see significant progress in many areas related to autoimmunity and importantly, an improved outlook for patients.

KEY POINTS

HLA molecules are among the most highly variable (polymorphic) proteins encoded in the genome.

HLA variability is a major factor in controlling immune responses.

HLA variability is likely to be directly responsible for a portion of the genetic susceptibility to autoimmune diseases.

Genetic associations including HLA associations must be interpreted with caution due to confounding factors such as linkage disequilibrium and hidden population stratification.

Large-scale genetic analysis of the entire genome for common genetic variants has revealed the presence of at least several hundred additional risk genes for autoimmunity, independent of HLA.

Many of the newly defined risk alleles predispose to multiple different autoimmune disorders.

A large fraction of the genetic risk for autoimmunity remains to be defined.

There has been an explosion of new information on the genetic factors underlying rheumatic diseases, with approximately 200 genes or chromosomal regions now convincingly associated with various autoimmune and inflammatory disorders. Most of these genetic associations have been discovered in the last few years, and as discussed in this chapter, it is highly likely that many hundreds, if not thousands, of additional genetic factors remain to be identified. The information base is now so large that many of the genetic details need to be left to be described in chapters on the specific diseases. Nevertheless, there are genetic commonalities among rheumatic disorders, and the basic principles underlying genetic analysis are an important base from which to evaluate the new findings. Therefore this chapter emphasizes approaches and concepts at least as much as genetic findings, in the hope that this will provide a foundation for keeping up with advances. The first section deals with the major histocompatibility complex (MHC) because the human leukocyte antigens (HLA) encoded in this region form a cornerstone for integrating both immunology and genetics into the understanding of rheumatic diseases. The second section of the chapter deals with genes outside of the MHC, with an emphasis on the approaches to gene discovery, as well as the implications of the new data for understanding disease pathogenesis. This should provide a background for interpreting new developments in the field,

Genetics of Rheumatic Diseases

PETER K. GREGERSEN

looking toward a future where genetic knowledge begins to be integrated into the daily practice of medicine.

MAJOR HISTOCOMPATIBILITY COMPLEX

The MHC, which encodes the human leukocyte antigens (HLAs), has been associated with susceptibility to many different diseases since the late 1970s. The chromosomal region containing the MHC was originally identified because of the ability of genes in this region to regulate transplant rejection¹ and to control the immune responses of mice and guinea pigs to simple antigens,² a series of observations that led to the 1980 Nobel prize. The HLA molecules and their counterparts in rodents were subsequently shown to be directly responsible for immune response differences between individuals and for determining the likelihood of graft rejection.¹⁻⁴ A large number of different HLA genes exist within the MHC, and they exhibit an enormous degree of structural variability. In addition to influencing immune response patterns, many of these alleles are associated with susceptibility to a wide spectrum of autoimmune diseases, making the MHC an essential starting point for anyone wanting to understand the genetics of rheumatic diseases.

Human Leukocyte Antigen Molecules and Antigen-Specific T Cell Recognition

The primary function of HLA molecules is the presentation of antigenic peptides to T cells. In the case of α/β T cells, most antigen recognition events involve the formation of a trimolecular complex consisting of the HLA molecule, its bound peptide, and the α/β T cell receptor (see Chapters 13 and 19). When this recognition occurs in the appropriate context, it may result in signal transduction and activation of the T cell. The requirement for MHC molecules to present antigenic peptides to T cells is frequently referred to as “MHC-restricted” T cell recognition. In each individual, T cells are generally restricted to recognize antigens presented by the person’s own HLA molecules. The allelic variations among different HLA molecules are a major factor accounting for differences in the types of antigenic peptides to which an individual responds or in the types of T cells that are used in an immune response.

Human Leukocyte Antigen Class I and Class II Molecules

The original serologic and biochemical studies of HLA molecules revealed the presence of two major isotypes: HLA class I and HLA class II. The basic structural features of

Figure 21-1 Schematic comparison of the structural features of major histocompatibility complex (MHC) class I and class II molecules. MHC class I molecules are anchored in the membrane by a single transmembrane segment contained in the 45-kD α chain. The MHC class I α chain is noncovalently associated with β_2 -microglobulin (β_2m). Among four external domains, three contain intramolecular disulfide bonds, as indicated. In contrast, MHC class II molecules consist of noncovalently associated α (32 kD) and β (28 kD) chains, both of which are anchored within the membrane. The overall domain organization of the two molecules is highly similar, however. The black dot (•) indicates glycosylation sites.

these classical HLA molecules are summarized in Figure 21-1. HLA class I molecules consist of a 45-kD α chain encoded within the MHC that is noncovalently associated with the 12-kD β_2 -microglobulin chain (encoded on chromosome 15). HLA class II molecules consist of noncovalently associated α (32 kD) and β (28 kD) chains, both of which are encoded within the MHC. HLA class I and class II molecules are cell surface glycoproteins, anchored to the membrane by hydrophobic transmembrane segments.

A major breakthrough in the understanding of HLA molecules came in 1987, when Bjorkman and colleagues^{5,6} reported the crystal structure of the HLA class I molecule, HLA-A2. This work was followed by the solution of other MHC class I and class II structures relevant to rheumatic disease.^{7,8} A side view of the class I molecule taken from Bjorkman's original paper is shown in Figure 21-2A. It can be seen that the base of the molecule (directly adjacent to the cell membrane) is formed by β_2 -microglobulin and the immunoglobulin-like α_3 domain. The α_1 and α_2 domains form a distinct cleft or groove at the top of the molecule. The function of this cleft is to bind antigenic peptides for presentation to T cells. A top view of this cleft is shown in Figure 21-2B. One can appreciate that the "floor" of the peptide binding cleft consists of β -sheets, whereas the "walls" of the cleft are bounded by extended regions of α -helical structure. The size of the HLA class I cleft is approximately 10 to 20 angstroms and generally can accommodate antigenic peptides that are 9 amino acids long.^{9,10}

HLA class II molecules have a structure that is highly similar to that of class I molecules, with a prominent peptide binding cleft at the membrane distal portion, sitting on top of a base formed by the α_2 and β_2 immunoglobulin-like

domains. The overall size and shape of the cleft in the two classes of HLA molecules are almost superimposable. However, subtle differences exist, particularly at the ends of the cleft, and this allows for some differences in the sizes of antigenic peptides that are presented by HLA class II molecules, compared with class I. Direct analysis of peptides bound to HLA class II molecules has shown that their size commonly varies from 12 to 19 amino acids.¹⁰ Thus relatively longer peptides lie in the cleft of class II molecules and may extend beyond the ends of the cleft, whereas class I molecules contain much shorter peptides that are buried within the cleft at either end.

Finally, x-ray crystallographic analyses of the entire tri-molecular complex consisting of an HLA molecule, its bound peptide, and the T cell receptor exist. Figure 21-3 shows an example of this structure for an HLA-DRB1*0401 allele presenting influenza Ha Peptide to its cognate α/β T

Figure 21-2 Three-dimensional structure of an HLA class I molecule, based on the X crystallographic analysis.⁵ **A**, Side view. A peptide-binding cleft is formed by the α_1 and α_2 domains at the top of the molecule. The α_3 and β_2 microglobulin (β_2m) domains are similar in structure to immunoglobulin domains; essentially, they act as a platform on which the peptide binding cleft rests, as well as providing contact sites for the CD8 molecule during CD8⁺ T cell recognition. **B**, Top view of the empty peptide-binding cleft. This "T cell view" of the MHC molecule would normally include a peptide bound within the cleft. Note the disulfide bond, which connects the α -helix of the α_2 domain with the floor of the cleft.

Figure 21-3 Ribbon diagram derived from the three-dimensional crystal structure of a the trimolecular complex of a human α/β T cell receptor (top, green), influenza Ha antigen peptide, and the MHC class II molecule, DRB1*0401.¹¹ Note that the peptide is contained within the peptide-binding cleft of the HLA-DR molecule. The polymorphisms associated with the “shared epitope” are located on the α -helical rim (DRB1 chain) of the peptide-binding cleft, where they may interact with either the bound peptide antigen or the T cell receptor.

cell receptor.¹¹ The Protein Data Bank (PDB) website (www.rcsb.org/pdb/home/home.do) provides three-dimensional versions of this HLA structure (Entry code 1J8H).

Human Leukocyte Antigen Class I and Class II Isotypes: Functional Correlates

HLA class II molecules have a restricted tissue distribution, generally limited to antigen-presenting cells of the immune system such as B cells, macrophages, dendritic cells, and some subsets of T cells. This reflects the fact that HLA class II molecules are primarily involved in presenting foreign antigens to CD4⁺ T cells during the initiation and propagation of the immune response. However, the expression of HLA class II molecules can also be induced on a variety of other cell types by inflammatory cytokines such as interferon- γ , enabling these cells to engage in antigen presentation to CD4⁺ T cells. In contrast, HLA class I molecules are widely distributed on all somatic cells, with the exception of red blood cells. This distribution reflects their predominant role in presenting antigen to CD8⁺ effector or cytotoxic T cells.

Another major functional difference between class I and class II molecules is related to the source of peptide antigens that are found in the antigen-binding cleft. In general, class I molecules present peptide antigens derived from proteins that are actively synthesized within the endoplasmic reticulum, whereas HLA class II molecules present antigens that are taken up from outside of the cell by endocytosis. These differences are reflected in the antigen processing machinery and the different trafficking patterns of class I and class II molecules inside the cell. Chapters 10 and 19 discuss this complex process in detail.

Genetic Organization of the Human Major Histocompatibility Complex

The human MHC extends over approximately 4 million base pairs on the short arm of chromosome 6 (6p21.3). The HLA class I and class II gene clusters are found in distinct locations, as indicated on the highly abridged genetic map shown in Figure 21-4. Only those genes that are traditionally associated with immune function are shown in Figure 21-4. The MHC, one of the most gene-rich regions in the human genome, has identified more than 200 genes.¹²

The HLA class I α -chain genes are on the telomeric side of the MHC including the classical class I genes, *HLA-A*, *HLA-B*, and *HLA-C*; these three genes are also referred to as the *class Ia* genes. Researchers have defined several other class I genes including the *HLA-G*, *HLA-E*, and *HLA-F* loci, also known as *class Ib* genes. Initially, experts considered these class Ib genes to be nonfunctional because they exhibit limited polymorphism. However, some of these genes clearly have significant immune functions. For example, *HLA-E* functions as a ligand for natural killer (NK) cell receptors.¹³ In a surprising twist, the cell surface expression of *HLA-E* molecules often depends on binding peptides derived from the signal sequence of class I molecules,¹⁴ but they can also present antigenic peptides to α/β TCR-bearing CD8⁺ cells.¹⁵ Despite its limited polymorphism, alleles of *HLA-E* may still affect responses to some viral infections.^{15,16}

The HLA class II genes are situated centromeric to the class I region and have a somewhat more complicated organization. The three major subregions of the class II cluster are designated DR, DQ, and DP. Each of these subregions contains a variable number of α - and β -chain genes. Particularly in the case of the DR subregion, this variability has led to confusion regarding the nomenclature to describe these genes. Experts have agreed on an international standard for this nomenclature regularly update it (see www.ebi.ac.uk/imgt/hla/).

The DR subregion contains a single α -chain gene, designated *DRA*, which does not exhibit significant allelic variation. In contrast, the genes encoding the DR β chains (*DRB*) are highly polymorphic and vary in number among different individuals in the population. The boxed area in Figure 21-4 shows several examples of common DR haplotypes. (A haplotype refers to a group of alleles at closely linked loci that are commonly inherited together.) Many of these *DRB* genes are nonfunctional pseudogenes (indicated by the symbol ψ), although all haplotypes contain at least one functional *DRB1* gene, and many haplotypes contain a second functional *DRB* gene (*DRB3*, *DRB4*, or *DRB5*).

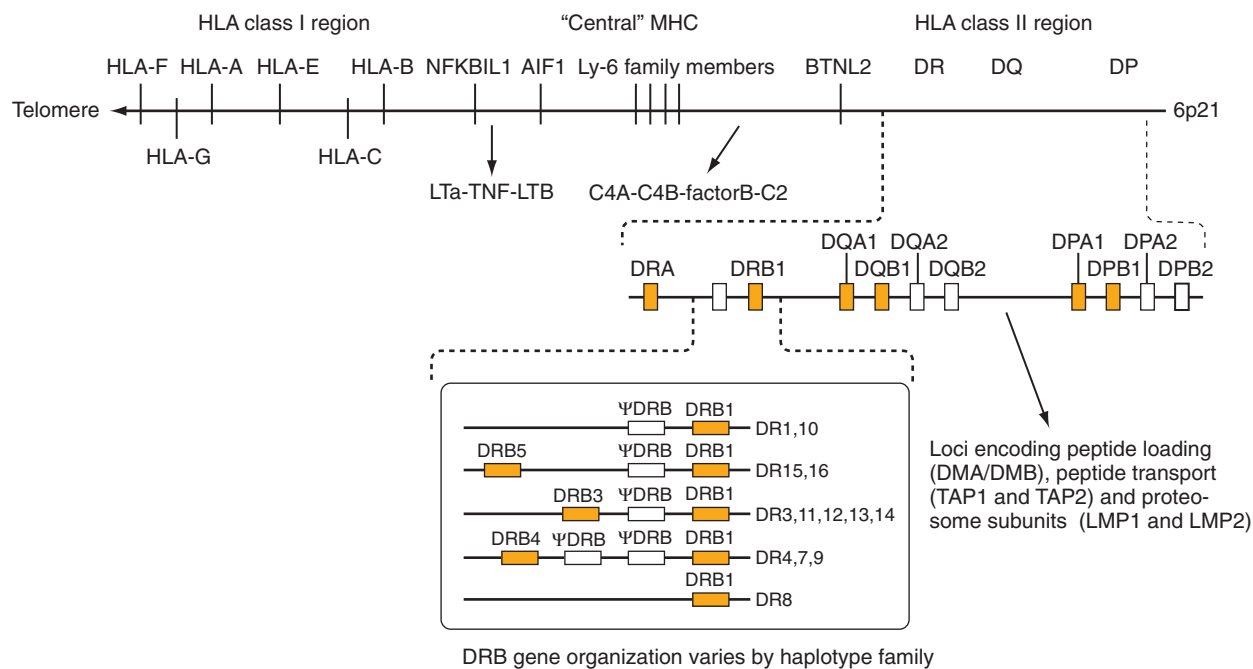

Figure 21-4 Map of the human major histocompatibility complex (MHC). The HLA class I and class II molecules are encoded in distinct regions of the MHC. The HLA class II region contains three subregions: DR, DQ, and DP. Each of these contains a variable number of α - and β -chain genes. HLA class II loci with known functional protein products are labeled in bold. In the case of DR, different numbers of DRB genes are present in different haplotypes. A summary of the most common of these is shown in the box. The DQ and DP subregions each contain one pair of functional α - and β -chain genes. A number of genes involved in antigen processing and presentation by class I molecules are situated between the DP and DQ subregions. The HLA class I region contains the three "classical" class I genes, HLA-A, HLA-B, and HLA-C, as well as other related class I molecules (see text). The "central MHC" also contains a number of genes related to immune function including the complement components (C4A, C4B, C2, and factor B), as well as tumor necrosis factor and lymphotoxin. Other potentially interesting genes in this region (*NFKB1L1*, *AIF1*, and *BTNL2*) are discussed in the text and reference 68.

The DQ subregion contains one pair of functional α - and β -chain genes, designated *DQA1* and *DQB1*. These two genes encode all the known HLA-DQ molecules. Significant expression of the protein products of the *DQA2* and *DQB2* loci has not been reported. A similar situation exists in the DP subregion, in which only the *DPA1* and *DPB1* genes give rise to known protein products, the HLA-DP molecules.

In addition to the HLA class II molecules, several other genes distributed within the class II region are involved in peptide antigen processing. The *TAP1* and *TAP2* genes have been of particular interest because they exhibit a modest degree of polymorphism and are involved in delivering peptides for loading onto HLA class I molecules.¹⁷ Other proteins encoded in this region are involved in peptide loading onto class II molecules¹⁸ such as the DM molecule (encoded by the *DMA* and *DMB* genes) and the DO/DN heterodimer (encoded by *DOB* and *DNA*).

The "central" MHC is located in between the MHC class I and class II regions. It contains a number of genes involved in immune function including those for tumor necrosis factor (TNF) and lymphotoxin, as well as the complement components C4A, C4B, C2, and factor B. The central MHC is quite gene dense, and it contains a significant number of other genes with potential relevance to immune function and disease susceptibility. However, the role of many genes in central MHC and class I regions is still largely unknown, and the interpretation of genetic associations with this region is complicated by the strong linkage disequilibrium across the MHC (see later).

Human Leukocyte Antigen Molecules Are Highly Polymorphic

One of the most dramatic features of the HLA system is the extreme degree of polymorphism at most of these loci. The formal definition of polymorphism (Table 21-1) usually requires that the most common allele at the locus does not exceed a frequency of 98%. In contrast, at many HLA loci, it is uncommon for a single HLA allele to exceed a frequency of 50% in the population. The number of different alleles present in the population is much larger than in any other known polymorphic locus encoding functional genes. For example, at the HLA-A locus, more than 100 different alleles have been reported; at HLA-B, the number of reported alleles exceeds 200. A similar degree of allelic diversity is seen at the *DRB1* locus and to a lesser degree at *DQA* and *DQB*.

For many years the naming of these various HLA alleles was a major source of confusion in the literature. The difficulty with the nomenclature stems in part from the different methods that have been used to define HLA polymorphisms. Originally, HLA class I alleles were detected through the use of alloantisera (see Table 21-1); the prefix "allo-" refers to genetic differences that exist between individuals of the same species. Alloantisera directed toward HLA molecules are commonly found in the context of pregnancy, in which the mother mounts an immune response against the "foreign" HLA molecules carried by the fetus (derived from the father). Anti-HLA responses are also seen after blood transfusion because the HLA molecules on the

Table 21-1 Glossary of Terms

Allele	Alternative form, or variant, of a gene at a particular locus
Alloantisera	Antisera that detect antigenic differences between individuals in the population; the term is most often used to refer to sera that detect antigenic (i.e., structural) differences among human leukocyte antigen molecules carried by different individuals
Haplotype	A group of alleles at adjacent or closely linked loci on the same chromosome that are usually inherited together as a unit
Heterozygote	An individual who inherits two different alleles at a given locus on two homologous chromosomes
Heterozygosity	A measure at a particular locus of the frequency with which heterozygotes occur in the population
Linkage	The tendency toward the co-inheritance within a family of two genes that lie near each other on the genome; complete linkage occurs when parents who are heterozygous at each locus are unable to produce recombinant gametes
Linkage disequilibrium	The preferential association in a population of two alleles or mutations that occurs more frequently than predicted by chance; linkage disequilibrium is detected statistically, and except in unusual circumstances, it implies that the two alleles lie near each other on the genome
Polymorphism	The degree of allelic variation at a locus within a population; specific criteria differ, but a locus is said to be polymorphic if the most frequent allele does not occur in > 98% of the population; occasionally, polymorphism can be used in the same way as allele to refer to a particular genetic variant
Penetrance	The conditional probability of disease (or phenotype) given the presence of a risk genotype

donor cells are highly immunogenic. In the case of HLA class II alleles, differences were originally detected using mixed lymphocyte responses. When T cells from a responder are mixed with lymphocytes from another individual, differences in HLA class II alleles cause the responder's T cells to proliferate. Data on mixed lymphocyte culture (MLC) typing dominated the early HLA literature, and it was the method first used to detect the HLA class II associations with RA.¹⁹ Subsequently, serologic methods were also employed to detect class II polymorphisms.

The current names of the HLA class I and class II alleles are attached to the specific DNA sequence and locus for each allele and are definitive. However, many older publications have used the serologically derived names for alleles. It is therefore important to have some concept of how these naming conventions are related. The modern definitive (sequence-based) allele names are derived from the older serologic names because the serologic techniques frequently detected whole groups of related alleles. Two examples of this are shown in Table 21-2. The designation of HLA-B27 was developed for people carrying an HLA-B allele that was recognized by the B27-specific alloantisera. However, sequencing of the HLA-B alleles carried by these individuals revealed the existence of at least 17 different alleles, 5 of which are listed in Table 21-2. A similar situation exists for HLA class II allele families such as HLA-DR4, also shown in Table 21-2. In this case, the DR4 allospecificity was already known to detect a number of different alleles

that could be further discriminated on the basis of MLC typing.²⁰ These have been defined and named by their sequence, as shown in Table 21-2. A full list of all HLA alleles at the major loci can be found at www.ebi.ac.uk/imgt/hla/.

Despite the precision of the molecular definition of HLA alleles, the old serologic names are often used in oral discussion because they are less cumbersome. For example, the DRB1*03011 allele is common in white populations (up to 10% in some populations) and is often referred to as simply DR3, after its original serologic designation. At least 16 distinct alleles are detected by such DR3 alloantisera, and therefore the term DR3 is imprecise. However, when used in the context of a discussion about white populations, DR3 is assumed to refer to the predominant DRB1*03011 allele.

HUMAN LEUKOCYTE ANTIGEN ASSOCIATIONS WITH RHEUMATIC DISEASES

Population-Association Studies and the Calculation of the Odds Ratio, an Estimate of Relative Risk

The ideal way to establish whether a genetic variant (allele) confers risk for a disease is by performing a prospective cohort study. In this kind of study, a group of individuals

Table 21-2 Comparison among Modern, Sequence-Based Nomenclature, and Older Naming Conventions for Class I and Class II Alleles Belonging to HLA-B27 and HLA-DR4 Serologic Groups*

HLA-B Locus: HLA-B27 Alleles		HLA-DRB1 Locus: HLA-DR4 Alleles		
Definitive Nomenclature Based on DNA Sequence	Serologic Designation (Defined by Alloantisera)	Definitive Nomenclature Based on DNA Sequence	Serologic Designation (Defined by Alloantisera)	Cellular Typing (Based on MLC)
B*2701	B27	DRB1*0401	DR4	Dw4
B*2702	B27	DRB1*0402	DR4	Dw10
B*2703	B27	DRB1*0403	DR4	Dw13
B*2704	B27	DRB1*0404	DR4	Dw14
B*2705	B27	DRB1*0405	DR4	Dw15

*The list of alleles is incomplete. The B27 allele family contains at least 17 members, and the HLA-DR4 allele family contains at least 35 members. See www.ebi.ac.uk/imgt/hla/ for a complete list of all HLA alleles.

MLC, mixed lymphocyte culture.

Table 21-3 Contingency Table for Cohort and Case-Control Studies*

Cohort Study		
	Disease	No Disease
Exposed	a	b
Not Exposed	c	d
Case-Control Study		
	Exposed	Not Exposed
Disease	a	b
No Disease	c	d

*a, b, c, d, number of individuals observed in each category.

carrying (exposed to) the allele is compared with a matched control group that does not carry the allele. These two groups are followed over time (preferably over a lifetime) to see if disease develops more frequently in the exposed group. The results can be displayed in a contingency table (Table 21-3). By examining the upper half of Table 21-3, it is apparent that the fraction of exposed individuals who get the disease is $a/(a + b)$, whereas the fraction of unexposed individuals who develop the disease is $c/(c + d)$. The ratio of these two fractions is known as the relative risk (RR) = $a/(a + b) \div c/(c + d) = (ac + ad)/(ac + bc)$. If the disease is rare in the population, ac is small and the RR is approximated by $(a \times d)/(b \times c)$, also referred to as the *cross-product*.

In reality, such prospective cohort studies are usually impractical and therefore a retrospective case-control design is used. In this type of study, subjects are initially identified according to whether they have the disease and individuals without the disease are the controls. The data can be tabulated as in the lower half of Table 21-3. In this case, the cross-product or $(a \times d)/(b \times c)$ is known as the odds ratio (OR). In practice, this quantity is often reported as the estimated RR because the cross-product is close to the RR when the disease is rare. An OR of 1 indicates that the genetic factor confers no risk for the disease. An OR less than 1 suggests that the genetic factor under study is negatively associated with the disease. (ORs of less than 1 are occasionally reported as the negative inverse value; an OR of +0.5 may also be reported -2.0.) With the exception of HLA-B27-associated diseases, most HLA associations with rheumatic diseases have ORs of less than 10. Several examples of typical HLA associations with rheumatic and autoimmune disorders are shown in Table 21-4.

Human Leukocyte Antigen Class I Associations: HLA-B27 and Spondyloarthropathies

One of the strongest and earliest²¹ reported HLA associations with the rheumatic diseases is the association of HLA-B27 with ankylosing spondylitis (AS). In white populations, more than 90% of patients with AS carry HLA-B27, in contrast to approximately 8% of normal individuals, giving estimated RR values of 50 to 100 or higher. The consistency of this finding across most ethnic groups lends support to the contention that the HLA-B27 alleles are directly involved in the pathogenesis of AS.^{22,23} HLA-B27 is also associated with reactive arthritis and with the arthritis seen in the context of inflammatory bowel disease. As shown in Table 21-4, the strength of these associations is lower in terms of estimated RR compared with ankylosing spondylitis.

The serologic specificity of HLA-B27 actually encompasses many distinct HLA class I alleles. These alleles differ from one another at a number of amino acid positions, most of which involve amino acid substitutions in and around the peptide binding pocket. This fact leads naturally to the question of whether there are differences among these B27 alleles in terms of disease association. Most data indicate that this is not the case, although there may be some exceptions in some populations.²² These exceptions may provide clues to the role of the HLA-B27 molecule in pathogenesis. Overall, however, it appears that most of the structural differences among the B27 alleles do not affect disease risk.²³

In recent years it has become apparent that increased risk for some severe drug reactions can be ascribed to HLA²⁴ including risk for allopurinol-associated Stevens-Johnson syndrome in Asian populations with HLA-B58.²⁵ These data imply the need for specific class I HLA typing before treatment with some medications.²⁶

Human Leukocyte Antigen Class II Associations with Autoimmune Diseases

A large number of HLA class II associations with autoimmune diseases were described over 2 decades ago.²⁷ RA has received particularly intense scrutiny over the years, but the precise reasons for the HLA associations with this disease are still unknown. In the case of systemic lupus erythematosus (SLE) and related illnesses, many of the HLA class II alleles are associated with the presence of specific autoantibodies or clinical phenotypes. Interestingly, the recent data in RA indicate that the major HLA-DR associations are

Table 21-4 Common HLA Associations with Rheumatic and Autoimmune Diseases

Disease	HLA Allele (Serologically Defined)	Approximate Allele Frequency in White Patients (%)	Approximate Allele Frequency in White Controls (%)	Approximate Relative Risk
Ankylosing spondylitis	B27	90	8	90
Reiter's syndrome	B27	70	8	40
Spondylitis in inflammatory bowel disease	B27	50	8	10
Rheumatoid arthritis	DR4	70	30	6
Systemic lupus erythematosus	DR3	45	20	3
Multiple sclerosis	DR2	60	20	4
Juvenile diabetes mellitus (type I)	DR4	75	30	6

with anti-CCP antibody positive disease, suggesting that control of autoantibody responses may be a primary mechanism underlying these associations in RA as well.

Rheumatoid Arthritis: HLA-DRB1 Associations and the “Shared Epitope”

Stastny¹⁹ reported the first associations of rheumatoid arthritis (RA) with HLA class II alleles in the 1970s. This was done using cellular²⁸ and antibody reagents²⁹ that are no longer routinely used for HLA typing; however, as discussed earlier, the nomenclature for HLA alleles still derives from these early typing methods. The DRB1*0401 allele (corresponding to the “Dw4” type in Stastny’s original report²⁸) was the first HLA polymorphism to be associated with RA. Numerous studies have generally confirmed that this allele is the most strongly associated with RA, at least in white populations.³⁰⁻³² However, several other HLA-DRB1 alleles have also been associated with RA, although the strength of these associations varies.^{31,33,34} In some ethnic groups, RA is not associated with HLA-DR4 alleles, but rather with HLA-DR1³⁵ or HLA-DR10.³⁶ Experts now widely accept that the following alleles are the major contributors to RA risk at the DRB1 locus: DRB1*0401, -0404, -0405, -0101, and -1001. In addition, minor variants of these alleles and others (e.g., DRB1*1402³⁷) may also contribute to susceptibility and DRB1*0901 is a susceptibility allele in Asians, where this allele is common.³⁸ Most of these risk alleles share a common sequence, as shown in Table 21-5. This consensus amino acid sequence 70Q or K-R-R-A-A74 has been termed the *shared epitope*.³⁹ This structural feature is located on the α -helical portion of the DR β chain in a position where it may influence both peptide binding and T cell receptor interactions with the DRB1 molecule. (In the case of the DRB1*1001 risk allele, one amino acid varies from this consensus by a conservative change, with an R at position 70, as does DRB1*0901, which is commonly associated with RA in Asian populations) (Table 21-6).

A number of different hypotheses have been advanced to explain the shared epitope association with RA.^{40,41} Two of these follow directly from knowledge about the role of HLA molecules in antigen presentation and immune regulation. Thus it has been suggested that a particular peptide antigen, or set of related antigens, may be involved in the initiation or propagation of RA, and that shared epitope

Table 21-6 Genotype Relative Risks of DRB1 Genotypes for Rheumatoid Arthritis

DRB1 Genotype	Relative Risk	P Value
0101/DRX	2.3	10 ⁻³
0401/DRX	4.7	10 ⁻¹²
0404/DRX	5	10 ⁻⁹
0101/0401	6.4	10 ⁻⁴
0401/0404	31.3	10 ⁻³³

From Hall FC, Weeks DE, Camilleri JP, et al: Influence of the HLA-DRB1 locus on susceptibility and severity in rheumatoid arthritis, *Q J Med* 89:821-829, 1996.

positive DRB1 alleles possess a unique, or enhanced, ability to bind or present these peptides to the immune system.⁴⁰ It has been difficult to address this hypothesis directly because the identity of these putative disease-causing peptide antigens is unknown. In view of the strong association of the shared epitope alleles with anti-CCP antibodies,⁴² it is of interest that citrullinated peptides may have a particular affinity for DRB1*0401 alleles.⁴³ A second major hypothesis posits that these risk alleles regulate the formation of the peripheral T cell repertoire, by acting to select for particular T cell receptors during thymic selection.⁴¹ There is elegant experimental evidence in humans to support a role for DR4 alleles in shaping the peripheral T cell repertoire.⁴⁴ However, it is unclear whether this effect on the TCR repertoire is really related to disease susceptibility. Researchers have proposed a number of other interesting hypotheses, involving molecular mimicry,^{45,46} allele specific differences in intracellular trafficking,⁴⁷ and regulation of nitric oxide production,⁴⁸ but these require further experimental confirmation.

The shared epitope hypothesis has come under scrutiny, with some investigators proposing a direct role for HLA-DQ polymorphisms,^{49,50} in part based on studies in transgenic mice.⁵¹ As can be seen in Figure 21-4, the HLA DQ α and β chains are encoded just centromeric to DRB1, and alleles at this locus are in strong linkage disequilibrium with DRB1 alleles. The strong linkage disequilibrium between the DR and DQ loci makes it difficult to tease apart the effects of DR versus DQ solely on the basis of population genetic studies; the arguments for a DQ effect generally depend on showing the enrichment of relatively rare genotypes in the RA patient group compared with controls. Overall, a primary role for DQ alleles is not strongly supported by large HLA association studies that have examined this issue⁵² and is not supported by more recent dense single-nucleotide polymorphism (SNP) mapping efforts within the MHC.⁵³ Rather, a possible additional role for the HLA-DP has been suggested.⁵³

Regardless of whether DQ or DP alleles are involved in RA susceptibility, it is quite clear that the shared epitope hypothesis is not a complete explanation for the HLA associations with RA. This is evident from the fact that not all SE-positive alleles carry the same degree of genetic risk and the strength of the association varies in different populations. In general, DRB1*0101 alleles carry lower levels of RR for RA than the DRB1*0401 and 0404 alleles,³² and yet DRB1*0101 is the major risk allele in some ethnic groups.^{54,55} The shared epitope itself does not appear to associate strongly with RA in African-American and some Hispanic

Table 21-5 Amino Acid Substitutions That Compose the Shared Epitope at Positions 70 through 74 of DRB1 Alleles Associated with Rheumatoid Arthritis

DRB1 Alleles	Amino Acid Position				
	70	71	72	73	74
0101	Gln	Arg	Arg	Ala	Ala
0401	—	Lys	—	—	—
0404	—	—	—	—	—
0405	—	—	—	—	—
0408	—	—	—	—	—
1402	—	—	—	—	—
1001	Arg	—	—	—	—

populations.^{56,57} Furthermore, certain combinations of DRB1 alleles carry especially high risk, as originally observed by Nepom.⁵⁸ Thus the combination of DRB1*0401 with *0404 carries a RR of higher than 30 in Caucasian populations.³² This compares with RR values in the range of 4 or 5 for either allele alone. Table 21-5 summarizes some of these relationships. Recently, attempts have been made to formalize the gradient of risk conferred by the various shared epitope alleles.⁵⁹ However, it remains unclear whether these effects are mediated by the HLA-DR molecules themselves or reflect the action of other genes on these haplotypes.

HLA-DQ Associations with Autoimmune Diseases

Many of the first HLA class II associations with autoimmune disorders were detected using alloantisera for HLA-DR alleles, as indicated in Table 21-4. However, as knowledge increased about the genetic organization of the class II region, it became apparent that for some diseases, the genetic associations are stronger with HLA-DQ alleles. For example, although juvenile diabetes does exhibit HLA associations with both HLA-DR4 and HLA-DR3, it is likely that a group of associated HLA-DQ alleles actually are responsible for these observations.⁶⁰ As discussed later, the HLA associations with particular autoantibodies in systemic lupus also probably reflect the effects of HLA-DQ alleles.

The DQ subregion presents special challenges for the newcomer to HLA because the old serologic nomenclature does not usually have a simple correlation with a group of alleles at a single locus. Because most of the HLA correlations with autoantibodies in lupus involve the DQ loci, it is important to understand this at the outset. The problem arises because both the α and β chains are polymorphic in DQ molecules. The serologic specificity of DQ2 may detect one of three closely related DQB1 alleles: DQB1*0201, DQB1*0202, or DQB1*0203. This is analogous to the DR serologic specificity detecting a group of related DRB1 alleles (see Table 21-2). However, in the case of DQ, the DQ2 serologic specificity also detects these alleles on several different haplotypes that may encode quite different DQ α chains. (This is different from HLA-DR molecules, in which the DR α -chain structure is constant and does not vary between haplotypes.) In white populations, the DQB1*0201 allele is commonly found on DR3 haplotypes (associated with DQA1*0501) and DR7 haplotypes (associated with DQA1*0201), but both these haplotypes would type serologically as DQ2 (Figure 21-5). Especially when reading the older literature and discussing DQ polymorphisms, it is important to distinguish serologically defined polymorphisms, which may vary within the group of alleles on the α and β chains, from polymorphisms defined by sequence at a specific locus (DQA1 or DQB1).

The HLA associations with the Ro (SS-A) and La (SS-B) autoantibody systems have been thoroughly studied. The anti-Ro response is present in 25% to 50% of patients with lupus⁶¹ and even more frequently in the setting of primary Sjogren's syndrome.⁶² Although early serologic studies indicated an association with HLA-DR3 and DR2, a detailed molecular analysis of these HLA haplotypes has provided evidence that HLA-DQ alleles in linkage

Figure 21-5 Combinatorial diversity of HLA-DQ molecules. The serologically defined “DQ2” molecule may contain the same DQ β chain paired with different DQ α chain alleles. This is different from HLA-DR molecules, in which the DR α chain does not vary among different MHC haplotypes.

disequilibrium with DR2 and DR3 are responsible for controlling this autoantibody response; heterozygous individuals who inherit a DR2-DQ1 haplotype and a DR3-DQ2 haplotype tend to have high anti-Ro antibody titers in the setting of lupus or Sjogren's syndrome.⁶³ The strongest associations involve a DQA1*0501-DQB1*0201 haplotype (frequently found in linkage disequilibrium with DR3) and a DQA1*06-DQB1*06 haplotype (frequently found in linkage disequilibrium with DR2). HLA-DQ associations have also been reported for other autoantibody systems such as antiphospholipid antibodies⁶⁴ and anti-Sm responses.⁶⁵ The overall pattern of HLA-DQ associations with these antibody responses is similar to those seen for anti-Ro responses, although the alleles involved are quite different.

Population-Association Studies: What Do They Mean?

Almost all of the studies on HLA and disease involve population associations that are detected by means of retrospective case-control studies. It is essential to understand the strengths and weaknesses of this approach to genetic analysis to judge the significance of these HLA associations. In general, there are three possible reasons for detecting an association between a particular allele and a disease, once acceptable statistical criteria are met (see later section).

First, the allele under investigation may be directly involved in the pathogenesis of the disease. This assumption actually underlies most of the foregoing discussion on HLA and rheumatic disease. The studies described reflect the search for a more precise definition of particular amino acid substitutions or unifying structural characteristics of disease-associated alleles. This effort derives from the idea that HLA alleles directly predispose to disease by virtue of their ability to control the immune response.⁴ As discussed earlier, this may involve a number of mechanisms including preferential peptide binding and the influence of MHC on thymic selection of the peripheral T cell repertoire.

A second reason that must be addressed with any new genetic association is the possibility that the result is an artifact of population stratification of patients and controls. The specific concern is that the control group may not be genetically matched to the disease group at loci that are unrelated to disease. This often results from a failure to
